ABSTRACT

We compute the synthetic 2-100 keV spectrum of an actively star forming galaxy. To this aim we use a luminosity function of point sources appropriate for starbursts (based on Chandra data), as well as the types of stellar sources and their corresponding spectra. Our estimates indicate that a Compton spectral component – resulting from scattering of SN-accelerated electrons by ambient FIR and CMB photons – could possibly be detected, in deep INTEGRAL observations of nearby starburst galaxies, only if there is a break in the spectra of the brightest ($L \geq 10^{38}$ erg s⁻¹) point sources.

Key words: Galaxies: X-ray { Galaxies: star formation.

1. INTRODUCTION

Star formation (SF) leads to X-ray emission on various spatial and temporal scales, including emission from O stars, X-ray binaries, supernovae and their remnants (SNRs), and galactic-scale emission from diffuse hot gas, and Compton scattering of FIR & CMB photons by SN-accelerated electrons. Integrated spectra of actively SF galaxies may show all these components as well as emission from an active nucleus (Rephaeli et al. 1991, 1995).

Persic & Rephaeli (2002; hereafter, PR02) have quantitatively assessed the roles of the various X-ray emission mechanisms in SFGs. They have used an equilibrium stellar-population synthesis model of the Galactic population of X-ray binaries to deduce birthrates for interacting binaries; these, combined with estimates of the duration of the X-ray bright phase, have allowed PR02 to make realistic estimates of the relative (Galactic) abundances of high-mass and low-mass X-ray binaries (HMXBs and LMXBs, in which the optical companions are main-sequence stars with $M > 8M_{\odot}$ and $M < M_{\odot}$, respectively). The abundance of SNRs (both Type II and Ia)

was also consistently estimated. From the literature PR02 derived typical spectra for these source classes. The spectral properties and relative abundances of the various classes of stellar sources allowed PR02 to calculate the composite X-ray spectrum arising from a stellar population of Galactic composition.

In addition to such "stellar" components, PR02 considered two diffuse, non-stellar contributions to a starburst (SB) X-ray spectrum.

(i) Thermal emission from the regions of interaction between SN-powered outgoing galactic wind and denser ambient ISM, mostly at energies > 1 keV, and thus of little concern to us here.

(ii) Non-thermal emission due to Compton scattering of the SN-accelerated relativistic radio-emitting electrons off the FIR and CMB radiation fields. The high SN rate in a SB is bound to yield high relativistic electron densities since SN shocks are known to be primary sites of cosmic ray acceleration. Moreover, in a SB environment the mean FIR energy density can be 10 times higher than that of the CMB. Compton scattering of a 100 μ m photon by a 1 GeV electron boosts the energy of the photon to 10 keV. A high density of electrons in a SB would obviously be reflected also in enhanced radio emission. If the same electron population produces both the radio and hard X-ray emission, then both spectra are expected to have roughly the same power-law index (Rephaeli 1979; Goldsmith & Rephaeli (1995). Compton X-ray emission gauges the current SFR since the electron Compton-synchrotron lifetime is approximately 10^8 yr (i.e. comparable to or shorter than a typical starburst duration).

PR02 determined that the 2-15 keV emission is dominated by LMXBs; this is not surprising, given that the synthetic spectrum was calibrated by that of a normal, quietly star forming galaxy like ours. Due to the long times between the formation and the onset of the X-ray phase (the optical companion is a subsolar main-sequence star) in LMXBs, their emission traces the higher, past Galactic SFR, and not the lower, current SFR. Thus in order to obtain an estimate of the current SFR, the spectral contri-

bution of LM XBs should not be included. As noted by PR02, at energies of approximately 30 keV (relevant for INTEGRAL) the SB spectrum is expected to be dominated by the Compton component.

Recent observations of nearby galaxies (mostly with the Chandra satellite) have revealed several X-ray point sources (XPSs) with 2–10 keV luminosities in the range $2 \cdot 10^{38} \text{ erg s}^{-1} < L < 10^{39} \text{ erg s}^{-1}$ (hereafter dubbed Very Luminous Sources: VLXs), and a few Ultra-Luminous Sources (ULXs), with $L > 10^{39} \text{ erg s}^{-1}$ (Fabbiano & White 2003)¹. Although their nature is not yet known, VLXs and ULXs are observed to be directly linked to current star formation activity (e.g., Zezas et al. 2002), and when identified, the optical counterpart of ULXs are O stars (Liu et al. 2002), thus establishing a link between HMXBs and ULXs. The spectra of VLXs and ULXs are characterized both as power-law in the range of interest, with index 2 and 1.3, respectively.²

2. CLASSES OF SOURCES OF X-RAY EMISSION

We briefly summarize the essential quantities needed to characterize each component of a SB spectrum:

a) O stars.

Luminosity: $L_{2-10} \approx 3 \cdot 10^{32-33} \text{ erg s}^{-1}$.

Spectrum: multi-T thermal ($kT \approx 0.5 \text{ keV}$).

(The contribution of O stars is very minor and will not be considered further here; see PR02.)

b) Supernova Remnants (SNRs).

Luminosity: $10^{36} < L_{2-10} < 10^{37} \text{ erg s}^{-1}$.

Spectrum: thermal with $kT \approx 2 \text{ keV}$, and $Z \approx Z_{\odot}$.

c) High-Mass X-Ray Binaries (HMXBs).

Luminosity: $10^{37} < L_{2-10} < 10^{38} \text{ erg s}^{-1}$.

¹These ranges correspond to Eddington luminosities for spherical accretion, respectively, 2 and 8 $M_{\odot}$ BHs. This is the range of BH masses that are thought to be attainable via ordinary stellar evolution. ULXs are called 'super-Eddington sources'.

²Broadly speaking, the VLXs and ULXs could, in fact, describe different luminosity/spectral states of BH X-ray binaries (BHXBs) as a function of the mass infall rate ($\dot{M}$) onto the BH, while the other relevant parameters are constrained within a much smaller range (e.g., BH mass $M \approx 5-10 M_{\odot}$, efficiency $0.3-0.6$). In fact, qualitatively speaking, the inverse correlation between luminosity and spectral index (i.e., softer spectra for higher luminosities) can be understood within the accretion model devised to explain the high X-ray luminosities of accretion-powered binary systems. The increase in luminosity is driven by an increase of $\dot{M}$, which in turn means a piling up of material around the emission region that leads to a higher Compton optical depth, and hence to a lower value of α , i.e. a softer spectrum. Namely, if a source is embedded in a plasma cloud of optical depth τ and temperature T_e , the spectral index α of the high-frequency wing of the spectrum of the escaping radiation is

$$\alpha = \frac{9}{4} + \frac{2m_e c^2}{3(\tau + 2)^2 kT_e} \approx 1.2$$

(Sunyaev & Titarchuk 1980; Shapiro et al. 1976).

Spectrum in 2–50 keV band:

$$f(\epsilon) / e^{[(\epsilon - \epsilon_F)/kT_e]} > \frac{c}{\epsilon}$$

where ϵ denotes energy (in keV), and with photon index $\alpha \approx 1.2$, cutoff energy $\epsilon_c \approx 20 \text{ keV}$, and e-folding energy $\epsilon_F \approx 12 \text{ keV}$.

d) Very Luminous X-Ray Sources (VLXs).

Luminosity: $2 \cdot 10^{38} < L_{2-10} < 10^{39} \text{ erg s}^{-1}$.

Spectrum in 2–10 keV band: power-law with (photon) index 2.

e) Ultra-Luminous X-Ray Sources (ULXs).

Luminosity: $10^{39} < L_{2-10} < 5 \cdot 10^{39} \text{ erg s}^{-1}$.

Spectrum in 2–10 keV band: power-law with (photon) index 1.3.

f) Compton scattering.

Luminosity: such that its flux at 10 keV is 0.1 of the total flux (see discussion in Persic & Rephaeli 2003).

Spectrum: power-law with (photon) index 1.8.

3. LUMINOSITY FUNCTION

The population of VLX and ULX sources in a galaxy is more abundant the more active is star formation in that galaxy. Specifically, if the point source integral luminosity function (XPLF) is described as $N(>L)/L$ (which corresponds to a differential XPLF of the type $\frac{dN}{dL} \propto L^{-(1+\alpha)}$), based on a wealth of Chandra observations it has been found that XPLFs are less steep in SFGs than in normal spirals and ellipticals. (For example, the two most nearby SB galaxies, have $\alpha \approx 0.5$ (M82) and $\alpha \approx 0.8$ (NGC 253), while normal spirals have $\alpha \approx 1.2$, and ellipticals have approximately $\alpha \approx 1.4$; see Kilgard et al. 2002.) So the integrated point source luminosity of SFGs is dominated by the highest-L sources (Colbert et al. 2003).

4. SYNTHETIC SPECTRUM

Given an (observed) XPLF, with the "stellar" component clearly sorted by luminosity, we can formally compute the integrated "stellar" spectrum according to

$$f(\epsilon) = \frac{\int \frac{dN(L)}{dL} L f(\epsilon; L) dL}{\int \frac{dN(L)}{dL} L dL};$$

where $f(\epsilon; L)$ are the above spectral profiles, normalized to the energy band 1–2 (here, 2–100 keV), where the luminosity L is defined. To this we add a diffuse Compton component. To be specific, we choose a power-law index $\alpha = 0.7$ for the XPLF (i.e. roughly the average between the values observed for M82 and NGC 253), and a Compton component which is 10% of the total flux at 10 keV. It is important to realize that our extrapolation of the observed spectra to 100 keV is just for the sake of computation.

Figure 1. The integrated 2-100 keV spectrum of a starburst. Shown in ascending order at 5 keV are the SNR, Compton, ULX, HMXB, and VLX components. The "stellar" components are normalized in energy flux in the 2-100 keV band. The Compton component has been normalized at 0.1 of the total flux at 10 keV. The spectrum is photoelectrically absorbed through an H I column density $N_{\text{H}} = 10^{22} \text{ cm}^{-2}$.

5. DISCUSSION

The resulting 2-100 keV spectrum is shown in Fig. 1. In the synthetic spectrum a conspicuous knee, due to the break in the HMXB spectrum, is immediately recognizable at 20 keV. If the ULX component, which turns out to lie very close to that of HMXBs for energies up to 20 keV, did turn out to have a similar break, then the knee in the synthetic spectrum would be sharper.

An important related consideration is that the Compton component will be swamped by the VLX and ULX components and thus practically undetectable by INTEGRAL, unless both "stellar" components exhibit a spectral break similar to that of HMXBs. It can be argued that the HMXB spectral break is related to the magnetic field strength, B , on the surface of the accreting neutron star: i) statistically, the cutoff energy, ϵ_c , is correlated with the observed cyclotron resonance energy, ϵ_0 , by $\epsilon_c \approx 2 \epsilon_0$: as the latter depends on B so will the former, which will then provide a measure of B (a most helpful feature in those cases where a resonant scattering feature is not observed (White et al. 1995); and ii) physically, the spectral break could be due to radiative transfer effects in a strong magnetic field (Boldt et al. 1976). If the magnetic fields are able to induce

20 keV spectral breaks in VLX-ULX spectra have strengths comparable to those observed in HMXBs³,

³A crude estimation suggests that for BH masses in the range $2-8 M_{\odot}$, which can be produced via ordinary evolution (i.e. through type II SN events) by progenitor stars with $M = 8-40 M_{\odot}$, the conservation of magnetic flux implies that for $B = 10-100 \text{ G}$ at the surface of the progenitor star, it will be $B = 10^{12}-10^{13} \text{ G}$ at the Schwarzschild radius, nearly irrespective of the BH mass. (See Mader & Meynet 1989 for the relevant quantities of the stellar progenitors). These values are consistent with those deduced for the magnetized neutron stars which are members of HMXB systems (see Boldt et al. 1976; White et al. 1995).

then a 20 keV cutoff is expected also in the spectra of VLX and ULX sources. Hence, the knee of the synthetic spectrum will turn out more marked and the Compton component will possibly stand out more clearly (at energies of approximately 30 keV). INTEGRAL measurements can possibly determine whether there is a break in VLX/ULX spectra.

On the other hand the Compton emission, in order to be discernible even in the absence of VLX/ULX spectral breaks, has to be stronger than assumed here. In our calculation we have assumed the Compton flux to be 0.1 of the total at 10 keV (which implies that it is 10% of the total 2-10 keV flux). This is a factor of 2 higher than the upper limit set by Griffith et al. (2000) on the Compton flux fraction of M 82 observed with Chandra (see Persic & Rephaeli 2003). It is possible that in SB galaxies high SN rates and dust temperatures enhance the Compton component such that it dominates the spectrum at energies higher than 30 keV.
