ABSTRACT

We present sensitive 1.3 cm radio continuum observations of the region OMC1 South (OMC-1S) in Orion using the Very Large Array in its B con quration. We detect eleven radio sources clustered in a 30° 30^{0} region, of which only three had been detected previously at radio wavelengths in deep 3.6 cm observations. The eight new radio sources are compact (s $0^{0}_{.1}$) and we set lower lim its to their spectral indices, > 0.8 0.3 (with S /), that suggest that they m ay be optically-thick H II regions. However, one of the new sources exhibits significant circular polarization, indicating that gyrosynchrotron emission with large positive spectral indices m ay be an alternative explanation. Furtherm ore, we nd that four other sources are associated with infrared sources of low bolom etric lum inosity that cannot drive an H II region. Finally, two of the sources previously detected at 3.6-cm are angularly resolved in the 1.3 cm in age and their major axes have position angles that align well with large scale out ow sem anating from OMC-1S. The radio source 143-353 has a major axis with a position angle consistent with those of the H H 202 and H H 528 ows, while the radio source 134-411 has a major axis with a position angle consistent with that of the low-velocity molecular out ow associated with the far-infrared source FIR 4.

1. Introduction

The OMC-1S region is a high-lum inosity (10^4 L) source at infrared and subm illim eter wavelengths in the O rion Nebula that is still actively form ing high-m ass stars (Bally, O'D ell, & M cC aughrean 2000). It is located about 1' to the SW of the Trapezium and several powerful molecular out ows (Ziurys, W ilson & M auersberger 1990; Schmid-Burgk et al. 1990; Rodr guez-Franco, M art n-P intado & W ilson 1999) appear to em anate from this region, probably driven by highly embedded young stars (Bachiller et al. 1996). Num erous H₂O m asers (G aum e et al. 1998) are also known to be present in OMC-1S.

The survey of proper-m otions in the Orion Nebula (Bally et al. 2000; O'Dell & Doi 2003) revealed that at least six relatively large Herbig-Haro out ows (HH 202, HH 269, HH 529, HH 203/204, HH 530, and possibly HH 528) are originating from a region only a few arcseconds across in OMC-IS that O'Dell & Doi (2003) locate at $_{2000} = 5^{h}35^{m}14^{s}56$, $_{2000} = 5 23'54"$ with a positional error of $1^{c0}5.0$ 'Dell & Doi (2003) refer to this region as the Optical Out ow Source (OOS). Although embedded objects (i. e., TPSC-I, Lada et al. 2000) have been detected in this region, the actual identi cation of the powering sources of the out ow s remains uncertain.

From their analysis of 3.6 cm radio continuum VLA archival observations of O rion, Zapata et al. (2004) found three faint sources in the OMC-1S region. Two of them (VLA 13 and VLA 15) are located near the position for the OOS (and thus may be related to the sources that power the multiple out ows that emanate from this region). The other source (VLA 10) is coincident, within the millimeter wavelength positional error, with the source FIR 4 (M ezger et al. 1990), the presum ed exciting source of the low-velocity CO out ow detected by Schmid-Burgk et al. (1990).

In this paper we present new observations of the OM C-1S region at 1.3 cm that reveala cluster of eleven sources, of which eight are new detections in the radio. This result supports the expectation that a cluster of young, possibly massive stars should be embedded here. Our results also allow us to improve our understanding of the nature of the three sources previously found at 3.6 cm by Zapata et al. (2004).

2. Observations

The observations were made with the Very Large Array of NRAO¹ in the continuum mode at 1.3-cm during 2003 D ecember 23 and 27. At these epochs, the VLA was in the B con guration. The phase center of the observations was $(2000) = 05^{h} 35^{m} 14^{s}.0$; $(2000) = 05 24^{0} 03^{00}$, very close to the center of the new radio cluster. The absolute amplitude calibrator was 1331+ 305 and the phase calibrator was 0541-056, with a bootstrapped ux density of 0.75 0.01 Jy.

The data were analyzed in the standard manner using the A IPS package of NRAO and self-calibrated in phase and amplitude. The images were made using only visibilities with baselines larger than 90 k, thus suppressing the emission of structures larger than 2° . This procedure is necessary given the presence of complex, extended emission in the region. Furtherm ore, we used the ROBUST parameter of IMAGR set to 0, in an optimal comprom ise between sensitivity and angular resolution. The resulting image ms was 70 Jy beam ¹ at an angular resolution of 0° .30 0° .25 with PA = 5. In the OMC-IS region we detected a total of 11 sources (see Figure 1). The positions, ux densities (at 1.3 cm and 3.6 cm), and spectral indices of these radio sources are given in Table 1. The 3.6 cm ux densities are from Zapata et al. (2004). To refer to these sources we have adopted a position-based nom enclature after the convention of 0 D ell & W en (1994). In Table 2 we list counterparts (objects within 0° .5 of the radio source) for the 1.3 cm sources. Only the radio source 143-353 has an optical counterpart in the HST optical images of 0 D ell & D oi (2003).

3. On the Nature of the 1.3 cm Sources

Following W indhorst et al. (1993), we roughly estim ate that the expected number of 1.3 cm background sources above a ux density of S is given by hN i' 1:0 10⁻³ (S=m Jy)⁻¹² arcm in ²: Then, the probability of nding a source with ux density equal or larger than 0.36 m Jy (the weakest source reported) in a 30⁻⁰ 30⁻⁰ region is only 0.001, so we conclude that m ost probably all sources are associated with 0 rion. O f the eleven sources detected at 1.3 cm in the eld, only three have been previously detected in the radio at 3.6 cm. The sources 131-411 (= VLA 10), 141-357 (= VLA 13) and 143-353 (= VLA 15) were detected in the sensitive 3.6 cm in age of Zapata et al. (2004). All the new eight sources have steep positive spectral indices, which explains why they are detected at 1.3 cm but not at 3.6

¹The National Radio A stronom y O bservatory is a facility of the National Science Foundation operated under cooperative agreement by A sociated Universities, Inc.

cm. From comparison with the 3.6 cm upper limits we set lower limits to their spectral indices, > 0.8 + 0.3 (with S /). This suggests that they may be optically-thick H II regions powered by embedded B-type stars. This proposition is consistent with the fact that three (136-359, 139-357, and 141-357) of the eight new ly found sources are closely associated with the water vapor masers reported by G aum e et al. (1998). However, one of the sources (140-410) was found to show large (20%) right circular polarization. This emission is believed to trace gyrosynchrotron emission from active magnetospheres of young, low mass stars. Furtherm ore, from the results of Sm ith et al. (2004) and Robberto et al. (2004) we nd that four other sources (136-356, 136-359, 139-357, and 144-351) are associated with infrared sources of low bolom etric luminosity that cannot drive an H II region. We are thus left with the possibility that some of these new sources are not optically-thick H II regions, but m ay be sources of gyrosynchrotron emission or ionized out ows from low-mass stars. We tried unsuccessfully to look for large temporal variations by comparing the D ecember 23 and D ecember 27 data. O bservations at several wavelengths and tim emonitoring are required to may be sources of these sources with steep, positive spectral indices.

4. Thermaljets

Only two sources are clearly resolved in the 1.3 cm data: 143-353 (= VLA 15), with deconvolved dimensions of 0.75 0.05 0.03 0.03; PA = 144 4, and 134-411 (= VLA 10), with deconvolved dimensions of 0.28 0.02 0.03; PA = 25 5. For the other radio sources we derive a typical upper limit of 0.16 for their angular size. As we will show, the orientation of these two sources suggests they are thermal jets that are powering important out ows in the region.

4.1. 143-353

W ithin the complex of six major out ows that originate from the OOS region (O D ell & Doi 2003), this feature aligns with both HH 202 and HH 528. HH 202 is the prominent HH object in the central region of the O rion N ebula and it was one of the rst in O rion to be identieed as such (Canto et al. 1980; M eaburn 1986). Rosado et al. (2001) have proposed that HH 202 form s a bipolar out ow with HH 203/204, but the fact that both HH 202 and HH 203/204 are blueshifted and the excellent alignment of the 1.3 cm source 143-353, with HH 202 on one side of the radio jet and HH 528 on the other side makes this suggestion less likely.

Examination of Figure 1 of O'Dell & Doi (2003) shows that the PA for HH 202 is 326 4 and that of HH 528 is 144 4, i.e. that they are almost exactly opposite in direction along a common axis and very well aligned with the major axis of the radio source 143-353 (144 4, see Figure 2). The proper motion data of O'Dell & Doi (2003) show that the tip of HH 202 is moving at 51 13 km s¹ towards 322 25 and the entire HH 528 object is moving at 25 14 km s¹ towards 159 35, which means that the two objects are moving away from one another and along their axis of orientation.

The radio source 143-353 has a nearly coincident optical counterpart, best seen in Figure 20 of Bally et al. (2000) as a bright emission line lam ent to the northwest from the source marked 9 in that gure. Our source 143-353 is the northwest portion of an irregular lam ent 3° 2 long, oriented towards PA = 323 10. The optical source is 0° 8 0° 2 in angular size, and is visible on HST in ages in H , [O III], [N II], [O I], and [SII]. Its orientation is PA = 310 10. The tangential motion of the entire lam ent is 16 4 km s¹ towards 323 17 (O'D ell & D oi 2003)

It is di cult to assign a source for any of the out ows from the OOS region on the basis of the extrapolation of orientation vectors as there are multiple objects within the error ellipse for the region. However, the additional information of the optical and radio alignment of 143–353 with both HH 202 and HH 528 suggests a relationship. In terms of the direction of motion of the optical counterparts of 143–353, it is plausible that HH 202 is being driven by the source that produces 143–353. The much lower tangential velocity of 143–353 would require that we are actually seeing the material entrained on the outside of a smaller, higher velocity jet, a condition that would apply if this jet were passing through the dense layer near the main ionization front of the nebula.

A connection with HH 528 is suggested by the orientations, but 143–353 is moving in the opposite direction. However, there may be a common source for both HH 202 and HH 528 which also produces 143–353. HH 202 is known to have a high blueshift (the most accurate and recent determ ination is by D oi, O'D ell& Hartigan 2004). A truly bipolar source would mean that HH 528 would have a similar high redshifted velocity, for which there is no evidence. However, we do see blueshifted components from two other (HH 269 and HH 529) opposite moving features coming out of the OOS region (D oi, O'D ell& Hartigan 2004). The east-west orientation of those ows indicates a di erent source within the OOS, but the velocities indicate that som emechanism is operating that allows opposite ow with common blueshifted components. If this sam e mechanism applies to HH 202{143–353{HH 528, then they too could be sharing a common source.

In general, therm al radio jets such as 143-353 are interpreted to m ark the position of the exciting source. Indeed, the fact that the source is not optically-thin suggests it is fairly

dense and most probably directly associated with the exciting star. However, it is also possible that 143-353 is just part of a long jet, displaced from the exciting star. If this is the case, there is a good candidate star for producing the 143-353 jet. This is the object 145-356, which has been detected at K' (Source 9; M cC aughrean & Stau er 1994), L (Source 2; Lada et al. 2000) N (Source 60; R obberto et al. 2004), and three IR bands (Source 3; Sm ith et al. 2004). There is no radio counterpart to this source. This apparently stellar source is positioned so that 143-353 lies 5° 1 at PA = 307. If one accepts the orientation of the extended jet and 143-353 as de nitive, then this star is an excellent candidate for the source. If the optical proper m otions indicate true tangential velocities, then the jet originated 700 years ago. If the proper m otion of H H 202 is adopted (which is the better assumption if the optical material is entrained gas on the edge of the jet), then the age of the jet is 220 years.

4.2. 134-411

As mentioned before, three of the eleven 1.3 cm sources had been detected previously at 3.6 cm (Zapata et al. 2004). One of them, 134-411 (= VLA 10) has a spectral index of 1.9 0.1, consistent with an optically-thick H II region. However, its position and orientation suggest that this source is driving the low-velocity monopolar molecular out ow (Schmid-Burgk et al. 1990) that is centered in the 1.3 mm continuum source FIR4 (M ezger et al. 1990), located at (2000) = $05^{h} 35^{m} 13^{s}.4$; (2000) = $05 24^{0} 13^{00}$. The PA of the major axis of 134-411 (see Figure 3) is 25 5, while that of them olecular out ow is 31 (Schmid-Burgk et al. 1990). The association of 134-411 with the out ow is also supported by its spatial coincidence with the cluster of high-velocity H₂O masers detected and discussed by G aum e et al. (1998).

5. Conclusions

Our results signi cantly alleviate the apparent lack of exciting sources of the multiple out ows that originate from OMC-1S. In particular, the source 143-353 could be driving the HH 202 and possibly the HH 528 ows, while the source 134-411 could be driving the low-velocity molecular out ow in the region. However, additional studies are required to identify the exciting sources of the multiple out ows and to rm ly establish the nature of the objects in this new cluster of compact, steep positive spectrum radio sources in O rion.

Fig. 1. VLA continuum in ages at 3.6 cm and 1.3 cm of the OM C1-S region. The position for the OOS (O'D elland D oi 2003) is indicated with a cross. The halfpower contour of the synthesized beam s are shown in the bottom left corner of the in ages. a. The faint sources 10, 13 and 15 were reported at 3.6 cm by Zapata et al. 2004. The contours are -5, 5 and 6 times 50 Jy beam ¹, the rm s noise of the in age. b. The objects 136-359, 136-356, 136-355, 137-347, 139-357, 139-409, 140-410 and 144-351, are rst reported as radio sources here. The contours are -5, 5, 6, 7, 8, 9, 10, 15, 20, 30 times 70 Jy beam ¹, the rm s noise of the in age.

Fig. 2. | VLA continuum in age at 1.3 cm of the source 143–353. The half power contour of the synthesized beam is shown in the bottom left contour. The contours are -4, -3, 3, 4, 5, 6, and 7 times 70 Jy beam ¹, the m snoise of the in age. This source is proposed to be driving the H H 202 and possibly the H H 528 out ows. The position angle of H H 202 is 326 4 and that of H H 528 is 144 4, aligning well with the position angle of the major axis of the radio source, which is 144 4.

Fig. 3. VLA continuum in age at 1.3 cm of the source 134-411. The half power contour of the synthesized beam is shown in the bottom left corner. The contours are -4, -3, 3, 4, 5, 6, 7, 8, 10, 15, and 20 times 70 Jy beam ¹, the rm s noise of the in age. This source is proposed to be driving the low-velocity monopolar molecular out ow associated with the far-infrared source FIR 4. The position angle of the molecular out ow is 31, in good agreement with the position angle of the molecular out 5.
