ABSTRACT

We study the distribution of the durations of gamma-ray bursts (GRBs) in the unified model of short and long GRBs recently proposed by Yamazaki, Ioka, and Nakamura. Monte Carlo simulations show clear bimodal distributions, with lognormal-like shapes for both short and long GRBs, in a power-law as well as a Gaussian angular distribution of the subjects. We find that the bimodality comes from the existence of the discrete emission regions (subjects or patchy shells) in the GRB jet. To explain other temporal properties of short and long GRBs, the subject parameters should depend on the angle in the whole jet.

Subject headings: gamma rays: bursts — gamma rays: theory

1. INTRODUCTION

The durations of gamma-ray bursts (GRBs) observed by BATSE show a bimodal distribution, which has led to a classification of GRBs into two groups: bursts with T_{90} durations < 2 s are called short GRBs, and those with durations > 2 s are called long GRBs (Kouveliotou et al. 1993; McBreen et al. 1994). If T_{90} directly reflects the active time of the progenitor of the GRB, different origins of short and long bursts are implied, such that the former arise from the binary neutron star mergers while the latter arise from the collapse of massive stars (e.g. Mészáros 2002; Zhang & Mészáros 2004).

The short and long bursts roughly consist of 25% and 75%, respectively, of the total BATSE GRB population. We should regard these fractions as comparable, considering possible instrumental effects on the statistics. If these two phenomena arise from essentially different origins, the similar number of events is just by chance. However, some observations have suggested that the short GRBs are similar to the long GRBs (e.g., Germany et al. 2000; Lazzati, Ramirez-Ruiz, & Ghisellini 2001; Nakar & Piran 2002; Lamb et al. 2003; Ghirlanda, Ghisellini, & Celotti 2004). Motivated by these facts, Yamazaki, Ioka, & Nakamura (2004b) proposed a unified model of short and long GRBs, even including X-ray flashes (XRFs) and X-ray-rich GRBs, and showed that it is possible to attribute the apparent differences of the light curves and spectra of these four kinds of events to the different viewing angles of the same GRB jet. This is a counter-argument against the current standard scenario of the origins of short and long GRBs.

In this paper, we perform Monte Carlo simulations to show that our unified model naturally leads the bimodal distribution of the T_{90} durations of GRBs. The paper is organized as follows. In § 2 we begin with a brief review of our unified model of short and long GRBs. The T_{90} duration distribution is calculated in § 3. Section 4 is devoted to discussions.

2. UNIFIED MODEL OF SHORT AND LONG GRBS

We briefly describe our unified model of short and long GRBs (for details, see Yamazaki, Ioka, & Nakamura 2004b). We assume that the GRB jet is not uniform but made up of multiple subjects, and that each subject causes a spike in the

observed light curve. This is an extreme case of an inhomogeneous jet model (Nakamura 2000; Kumar & Piran 2000). Let us consider a subject with the opening half-angle θ_{sub} moving with Lorentz factor γ , observed from the viewing angle ψ . Because of relativistic effects, the subject emission becomes dim and soft when ψ is larger than $\theta_{\text{sub}} + \gamma^{-1}$ (Ioka & Nakamura 2001). The *effective* angular size of its emission region is $(\theta_{\text{sub}} + \gamma^{-1})^2$, which is larger than the geometrical size of θ_{sub}^2 . For the multiple subject case, the crucial parameter is the multiplicity (n_s) of the *effective* emission regions along a line of sight. If many subjects point toward us (i.e., $n_s \gg 1$) the event looks like a long GRB, while if a single subject points toward us (i.e., $n_s = 1$) the event looks like a short GRB.

Below we give a typical set of parameters for the temporal and spatial configurations of the GRB jet to demonstrate which type of event is observed depending on n_s . We suppose that N_{tot} subjects are launched from the central engine of the GRB randomly in time and directions and that the whole jet consists of these subjects. We introduce a spherical coordinate system $(r; \theta; \phi)$ in the central engine frame, where the origin is the location of the central engine, and $\theta = 0$ is the axis of the whole jet. The axis of the j th subject ($j = 1; \dots; N_{\text{tot}}$) is denoted by $(\theta_j; \phi_j)$, while the direction of the observer is denoted by $(\theta_{\text{obs}}; \phi_{\text{obs}})$. We suppose that the j th subject departs at time $t_{\text{dep}}^{(j)}$ from the central engine and emits at radius $r = r^{(j)}$ and time $t = t_{\text{dep}}^{(j)} + r^{(j)}/c$. The departure time of each subject $t_{\text{dep}}^{(j)}$ is assumed to be homogeneously random between $t = 0$ and $t = t_{\text{dur}}$, where t_{dur} is the active time of the central engine measured in its own frame and is set to $t_{\text{dur}} = 20$ s. The emission model for each subject is the same as the uniform jet model in Yamazaki, Ioka, & Nakamura (2003a). For simplicity, all the subjects are assumed to have the same intrinsic luminosity and opening half-angle $\theta_{\text{sub}}^{(j)} = 0.02$ rad, and the other properties are $\gamma^{(j)} = 100$, $r^{(j)} = 3 \times 10^3$ cm, $\theta_B^{(j)} = -1$, $\phi_B^{(j)} = -2.5$, and $h_0^{(j)} = 500$ keV for all j . The opening half-angle of the whole jet is set to $\theta_{\text{tot}} = 0.3$ rad. We randomly spread $N_{\text{tot}} = 350$ subjects following the angular distribution function of the subjects as

$$\frac{dN}{d\theta} n(\theta; \phi) = \frac{n_c}{n_c (\theta - \theta_c)^{-2}}; \quad 0 < \theta < \theta_c; \quad \theta_c < \theta < \theta_b; \quad (1)$$

where $\theta_b = \theta_{\text{tot}} - \theta_{\text{sub}}$ and $\theta_c = 0.02$ rad (see also

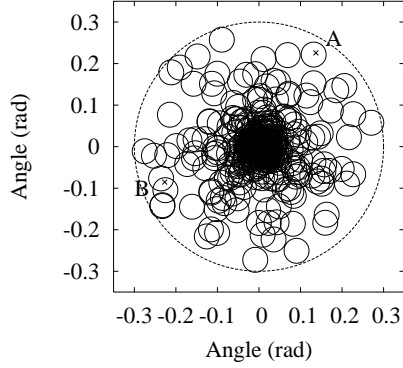

FIG. 1.— Angular distribution of $N_{\text{tot}} = 350$ subjects confined in the whole GRB jet in our simulation. Each subject is located according to the power-law distribution function of eq.(1). The whole jet has an opening half-angle of $\theta_{\text{tot}} = 0.3$ rad. The subjects have the same intrinsic luminosity and opening half-angles $\theta_{\text{sub}} = 0.02$ rad, and the other properties are $\beta = 100$, $r = 3 \times 10^{13}$ cm, $\beta_{\text{sub}} = -1$, $\beta_{\text{sub}} = -2.5$ and $h_0 = 500$ keV. The effective angular size of the subjects are represented by the solid circles, while the whole jet is represented by the dashed circles. The examples of lines of sight A and B are shown in the figure, while C is located at $(-0.04 \text{ rad}; 0.04 \text{ rad})$ and D is close to the center of the whole jet.

Rossi, Lazzati & Rees 2002; Zhang & Mészáros 2002). Figure 1 shows an example of the angular distribution of the effective emission regions of the subjects in our calculation. Most of the subjects are concentrated near the $\theta = 0$ axis (i.e., the multiplicity in the center $n_s = 100$). For our adopted parameters, isolated subjects exist near the edge of the whole jet, and there are some directions in which no subject is launched.

Figure 2 shows examples of the observed light curves in the 50–300 keV band, each of which corresponds to the lines of sight A, B, C, and D in Figure 1. The coordinate $(\theta_{\text{obs}}; \theta'_{\text{obs}})$ of C is $(-0.04 \text{ rad}; 0.04 \text{ rad})$, and D is close to the center of the whole jet. If many subjects point in the direction of the line of sight, such as in the cases of C ($n_s = 15$) and D ($n_s = 97$), we see a spiky temporal structure. In the case of B ($n_s = 2$), the event consists of the distinct emission episodes. These are identified as long GRBs. If only one subject points toward us, like in the case of A ($n_s = 1$), the contributions to the observed light curve from the other subjects are negligible because of relativistic beaming effect, so that the observed gamma-ray fluence and duration are both about a hundredth of the typical values of long GRBs. These are quite similar to the characteristics of short GRBs. In addition, when the line of sight is away from any effective subject regions (i.e., $n_s = 0$), the soft and dim prompt emission is observed because of relativistic Doppler effect and beaming effect, which is identified as an XRF or an X-ray-rich GRB (Ioka & Nakamura 2001; Yamazaki, Ioka, & Nakamura 2002, 2003a, 2004a,b; Yamazaki, Yonetoku, & Nakamura 2003b).

3. DISTRIBUTION OF T_{90} DURATION

We perform Monte Carlo simulations to show that our unified model can explain the observed bimodal distribution of T_{90} durations of GRBs. We fix the subjects' configuration as in Figure 1. We vary only the line of sight of the observer and calculate the T_{90} duration for each observer in the 50–300 keV band. We generate 2000 lines of sight with $0 < \theta_{\text{obs}} < 0.35$ rad according to the probability distribution of $\sin \theta_{\text{obs}} d\theta_{\text{obs}} d\theta'_{\text{obs}}$. We then select only hard events, whose observed hardness ratio is $S(2-30 \text{ keV})/S(30-400 \text{ keV}) < 10^{-0.5}$ (Sakamoto et al. 2004). The other soft events are clas-

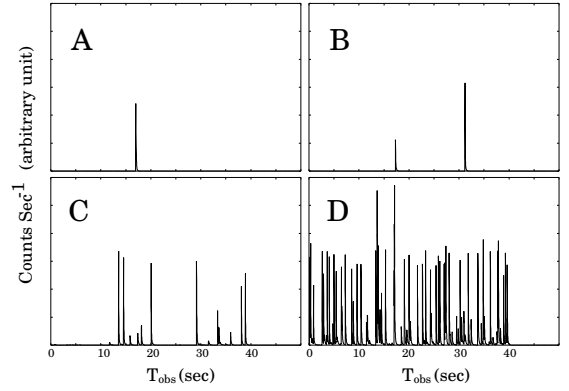

FIG. 2.— Observed light curves in the 50–300 keV band for the lines of sight shown in Fig. 1: A with $n_s = 1$ (upper left), B with $n_s = 2$ (upper right), C with $n_s = 15$ (lower left), and D with $n_s = 97$ (lower right). The sources are located at $z = 1$. The T_{90} durations are 0.25 s for A, 14.1 s for B, 25.4 s for C, and 37.8 s for D.

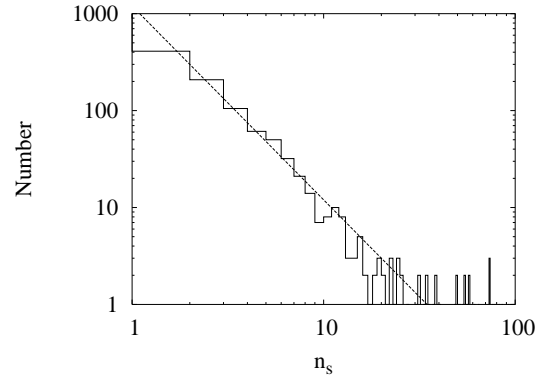

FIG. 3.— Distribution of multiplicity n_s for the angular distribution of the subjects of Fig. 1. The dashed line represents the analytical estimate of the n_s^{-2} line (see text).

sified as XRFs or X-ray-rich GRBs, which are observed when all subjects are viewed off-axis.

Figure 3 shows the distribution of n_s in our simulation. The multiplicity n_s is roughly proportional to $n(\theta_{\text{obs}}; \theta'_{\text{obs}})$. Then the distribution of n_s is given by $P(n_s) / \sin(\theta_{\text{obs}})(d\theta_{\text{obs}}/dn_s) \propto n_s^{-2}$ (Fig. 3, dashed line). We first consider the T_{90} distribution in the case in which the redshifts of all the sources are fixed at $z = 1$ for simplicity. The result is shown in Figure 4. One can see a bimodal distribution of T_{90} clearly. Which type of burst is observed, long or short, depends on n_s , and the distribution of n_s is unimodal. Then why does the distribution of the duration become bimodal? The reason for the scarcity of the events for $1 < T_{90} < 10$ s is as follows. Let us first consider the event with $n_s = 1$. In this case the T_{90} duration does not vary significantly around 0.25 s when $\beta_{\text{sub}} < \beta_{\text{sub}}^{\text{max}}$, which is determined by the angular spreading time of a subject. As the viewing angle increases, T_{90} increases (Ioka & Nakamura 2001). When $\beta_{\text{sub}} \approx \beta_{\text{sub}}^{\text{max}} + 1$, however, the emission becomes soft and dim, so that the event will not be detected as a GRB (Yamazaki, Ioka, & Nakamura 2002, 2003a; Yamazaki, Yonetoku, & Nakamura 2003b). The T_{90} takes a maximum value of 0.75 s when $\beta_{\text{sub}} \approx \beta_{\text{sub}}^{\text{max}} + 1$. We confirm that $n_s = 1$ for almost all $T_{90} < 1$ s events. Next let us consider the $n_s = 2$ case. The example of the light curve for this case is Figure 2b, and the T_{90} is 14.1 s. The T_{90} duration is roughly given by the interval between the arrival times of

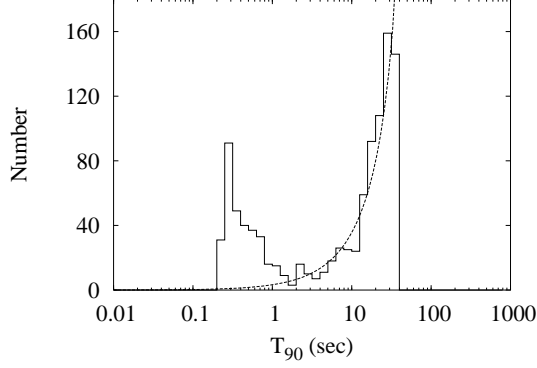

FIG. 4.— T_{90} duration distribution in the 50–300 keV band of hard events with observed fluence ratio $S(2-30 \text{ keV})/S(30-400 \text{ keV}) < 10^{-0.5}$. The jet model is the power-law. All sources are located at $z = 1$. The dashed line represents the analytical formula for the long GRBs, given by eq. (A2).

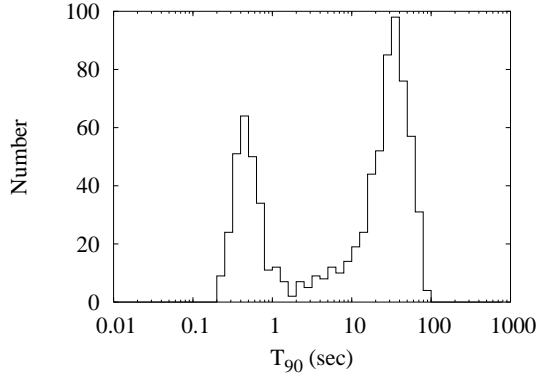

FIG. 5.— Same as Fig.4 but the source redshifts are varied according to the cosmic star formation rate (see text for details). Both short and long GRBs look like lognormal distributions.

two pulses. Since the two pulses arrive sometime in the range $0 < T_{\text{obs}} < T_{\text{dur}}$, where T_{dur} is the active time of the central engine measured in the observer's frame, $T_{\text{dur}} = (1+z)t_{\text{dur}} = 40 \text{ s}$, the mean interval is $40/3 = 13.3 \text{ s}$. This means that the duration of the $n_s = 2$ event is much longer than that for $n_s = 1$. For $n_s = 3$, the mean duration is longer than 13.3 s . The typical example is Figure 2c for $n_s = 15$, with $T_{90} = 25 \pm 4 \text{ s}$. This is the reason we have few events for $1 < T_{90} < 10 \text{ s}$. The maximum value of T_{90} is T_{dur} . For the long bursts, the distribution function of T_{90} durations can be derived from a simple probability argument (see the Appendix A for details). The dashed line in Figure 4 represents the analytical formula of equation (A2). On the other hand, the distribution function of the short bursts seems to be too complicated to calculate analytically, since it sensitively depends on the jet configurations, such as the angular distribution and the intrinsic properties of the sub-jets.

The ratio of events of the short GRBs and the long GRBs is about 2 : 5, which can be explained as follows (Yamazaki, Ioka, & Nakamura 2004b). The event rate of the long GRBs is in proportion to the effective angular size of the central core $\#_{\text{c}} \pi \theta_{\text{eff}}^2$ (0.15 rad^2 , where $n_s = 2$). The event rate of the short GRBs is in proportion to $M(\theta_{\text{sub}} + \theta_{\text{c}})^2$, where M is the number of isolated subjects in the envelope of the core and $M = 10$ in our present case. Then the ratio of event rates of the short and long GRBs becomes $M(\theta_{\text{sub}} + \theta_{\text{c}})^2$:

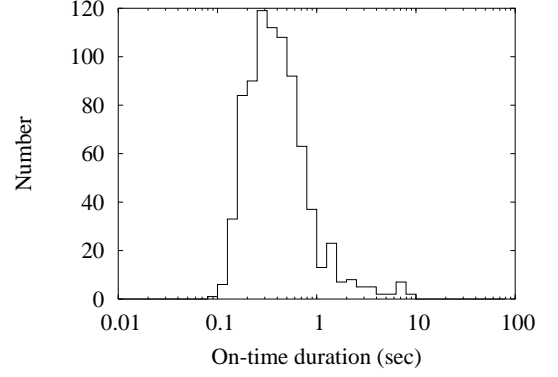

FIG. 6.— ON time duration distribution in the 50–300 keV band of hard events with observed fluence ratio $S(2-30 \text{ keV})/S(30-400 \text{ keV}) < 10^{-0.5}$. We calculate the ON time duration as the time during which the emission is larger than 10% of the peak flux. The subject distribution is given by the power-law form. The source redshifts are varied according to the cosmic star formation rate.

$$\#_{\text{c}} \pi \theta_{\text{eff}}^2 : 2 : 5.$$

In reality, we should take into account the source redshift distribution. We assume that the rate of GRBs is in proportion to the cosmic star formation rate. We adopt the model SF2 in Porciani & Madau (2001), in which we take the standard cosmological parameters of $M = 0.3$ and $\Omega = 0.7$. Figure 5 shows the result. The distribution is again clearly bimodal, and the shapes of the short and long GRBs look like lognormal distributions. The ratio of the number of short and long GRBs is about 2 : 5 in this case as well. The dispersion of the lognormal-like distribution seems relatively small compared to the observations. This is ascribed to simple modeling in this paper. We fix the jet configuration and use the same intrinsic properties of the subjects. If we vary t_{dur} for each source and θ_{c} for each subject randomly, for example, the dispersion of lognormal-like T_{90} duration distribution will increase from the general argument that the dispersion of the lognormal distribution increases with the increase of the number of the associated random variables (Ioka & Nakamura 2002). In more realistic modeling the observed dispersion will be reproduced.

4. DISCUSSION

We have investigated the T_{90} duration distribution of GRBs under the unified model of short and long GRBs proposed by Yamazaki, Ioka, & Nakamura (2004b), and found that the model can reproduce the bimodal distribution observed by BATSE. In our model, the crucial parameter is the multiplicity (n_s) of the subjects in the direction of the observer. The duration of an $n_s = 1$ burst is determined by the angular spreading time of one subject emission, while that of an $n_s = 2$ burst is determined by the time interval between the observed first pulse and the last one. These two different time scales naturally lead a division of the burst T_{90} durations into the short and long ones. We also performed a similar calculation for a Gaussian distribution, $n(\#; \sigma) = n_c \exp -(\# - \#_c)^2 / 2\sigma^2$, and found that the T_{90} duration distribution is bimodal in the same way as for the power-law subject model.

Let us make another comparison of our model with BATSE data. Mitrofanov et al. (1998) have computed the distribution of the observed pulse number (denoted by n_p in their paper) and found that it is unimodal. If the n_p distribution were compared with the n_s distribution, our model might be compatible with the observations, although some long GRBs

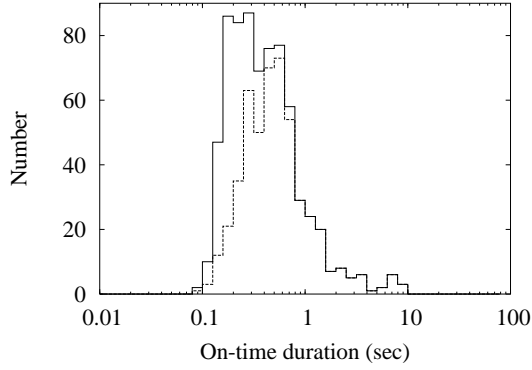

FIG. 7.— Same as Fig. 6, but the intrinsic luminosity of each subject is assumed to be $A^{(j)} = A_0 (= \text{constant})$ for $\# < 0.15$ rad and $A^{(j)} = A_0(\# = 0.15)^{-6}$ for $0.15 \text{ rad} < \# < \#_b$, where A_0 is in arbitrary unit. Then we only take the events with peak flux larger than 3×10^{-4} of the maximum peak flux that has appeared in the calculation. The dashed line represents $n_s = 2$ events.

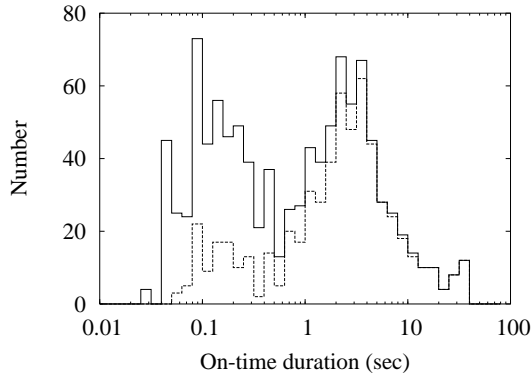

FIG. 8.— Same as Fig. 6, but the emission radius $r^{(j)}$ of each subject is assumed to be $r^{(j)} = 3 \times 10^{14}$ cm for $\# < 0.15$ rad and $r^{(j)} = 3 \times 10^{14}(\# = 0.15)^{-6}$ cm for $0.15 \text{ rad} < \# < \#_b$. The source redshifts are fixed as $z = 1$. The solid line represents all the events, while the dashed line represents $n_s = 2$ events.

are identified as $n_p = 1$ events. They also derive the distribution of the ON time duration—defined as the time during which the emission is larger than 40% of the peak flux—and found it bimodal. Furthermore, they argue that the mean pulse widths of short and long GRBs are different. On the other hand, we compute the ON time duration distribution in the context of our theoretical model and found it unimodal (see Fig. 6), which is expected since the pulse widths are almost the same. However, there are several observational implications that the distances to short GRBs detected with BATSE are smaller than those of long GRBs (e.g., Tavani 1998; Ghirlanda, Ghisellini, & Celotti 2004), although this is controversial. Then the observed pulse widths for short and long GRBs might be different because of the redshift factor. To give an example, let us assume that the intrinsic luminosity of each subject in the core region of the whole jet is larger than that in the periphery of the whole jet and count only the GRB

events with peak flux larger than 3×10^{-4} of the maximum peak flux in our simulation. The result is shown in Figure 7, in which we find that the effect of the peak flux cut off contributes to the bimodality of the ON time duration distribution.

At present, the observationally inferred bimodality of ON time duration is not explained in our current model, in which all the subjects have the same intrinsic luminosity, the same opening half-angle, the same gamma factor, the same emission radius, and so on. This is an extreme modeling for simple calculation. In reality, they may depend on the off-axis angle in the whole jet; so may the pulse widths. Furthermore, Nakar & Piran (2002) investigated the pulse widths of GRBs using 2 ms time resolution and report that short GRBs also consist of several pulses. This can be incorporated into our model by assuming that a subject radiates successive emissions rather than one instantaneous emission. Then the pulse width with 64 ms resolution (which is used in Mitrofanov et al. 1998) will be determined by the active time of the subject. If the pulse widths from the subjects in the central part are larger than those in the periphery, the bimodality of ON time duration distribution can be explained. For example, we assume that the emission radius $r^{(j)}$ is larger for the core region than for the periphery. Figure 8 is the result, which shows the bimodal-like distribution. Therefore, as we show in two examples (Figs. 7 and 8), some modifications of our model contribute to the bimodality of the ON time duration, so that the current observed ON time duration distribution is not inconsistent with our model. We hope that in the future more sophisticated modeling will reproduce the observed ON time duration distribution.

It has commonly been said that the observed bimodal distribution of the T_{90} durations of BATSE bursts shows the different origins of short and long GRBs. However, the bimodal distribution is also available as a natural consequence of our unified model of short and long GRBs. The clear prediction of our unified model is that short GRBs are associated with energetic supernovae (SNe), since the association of long duration GRBs with SNe is strongly suggested (Galama et al. 1998; Stanek et al. 2003; Hjorth et al. 2003; Della Valle et al. 2003). Indeed, one of the short GRBs shows possible association with a SN (Germany et al. 2000). Even if the SNe are not identified with short GRBs because of some observational reasons, we predict that the spatial distribution of short GRBs in host galaxies should be similar to that of the long GRBs. Another prediction is that short GRBs have the same total kinetic energies as long GRBs, which might be confirmed by radio calorimetry (Berger et al. 2003).

We are grateful to the referee D. Lazzati for instructive comments. We would like to thank T. Piran for useful discussions. This work was supported in part by a Grant-in-Aid for the 21st Century COE “Center for Diversity and Universality in Physics” and also by Grants-in-Aid for Scientific Research of the Japanese Ministry of Education, Culture, Sports, Science, and Technology 05008 (R. Y.), 14047212 (T. N.), and 14204024 (T. N.).

APPENDIX

ANALYTICAL ESTIMATE OF THE INTRINSIC T_{90} DISTRIBUTION OF THE LONG BURSTS

In this Appendix we derive the analytical distribution function of the T_{90} durations of the long GRBs when all sources are assumed to be at $z = 1$. At first we consider for a given n_s (≥ 2). Each subject causes one pulse, whose shape is a γ -function for simplicity. In the present case the arrival time of the pulse from each subject is random in the range $0 < T_{\text{obs}} < T_{\text{dur}}$. For a given

T_{90} , the first pulse is required to arrive within $T_{\text{dur}} - T_{90}$. The arrival time of the last pulse is determined as the time T_{90} after the first pulse. The rest of the pulses are required to arrive within the range of T_{90} . Thus, the probability function of T_{90} for a fixed n_s is approximately given by

$$P_{n_s}(T_{90})dT_{90} = n_s(n_s - 1) \frac{T_{\text{dur}} - T_{90}}{T_{\text{dur}}} \frac{T_{90}}{T_{\text{dur}}}^{n_s-2} \frac{dT_{90}}{T_{\text{dur}}} : \quad (\text{A1})$$

For the power-law angular distribution of the subjects the distribution function of n_s is proportional to n_s^{-2} , so that we get

$$P(T_{90})dT_{90} / \sum_{n_s=2}^{\infty} n_s^{-2} P_{n_s}(T_{90})dT_{90} = \frac{(T_{90}=T_{\text{dur}}) + [1 - (T_{90}=T_{\text{dur}})] \log[1 - (T_{90}=T_{\text{dur}})]}{T_{90}=T_{\text{dur}}} \frac{dT_{90}}{T_{90}} : \quad (\text{A2})$$

The distribution function of n_s for the Gaussian angular distribution of the subjects can be obtained in a similar way.
