## ABSTRACT

We present analysis of the large sample of variable red giants from the Large and Small Magellanic Clouds detected during the second phase of the Optical Gravitational Lensing Experiment (OGLE-II) and supplemented with OGLE-III photometry. Comparing pulsation properties of detected objects we find that they constitute two groups with clearly distinct features. In this paper we analyze in detail small amplitude variable red giants (about 15 400 and 3000 objects in the LMC and SMC, respectively). The vast majority of these objects are multi-periodic. At least 30% of them exhibit two modes closely spaced in the power spectrum, what likely indicates non-radial oscillations. About 50% exhibit additional so called Long Secondary Period.

To distinguish between AGB and RGB red giants we compare PL diagrams of multi-periodic red giants located above and below the tip of the Red Giant Branch (TRGB). The giants above the TRGB form four parallel ridges in the PL diagram. Among much more numerous sample of giants below the TRGB we find objects located on the low luminosity extensions of these ridges, but most of the stars are located on the ridges slightly shifted in  $\log P$ . We interpret the former as the second ascent AGB red giants and the latter as the first ascent RGB objects. Thus, we empirically show that the pulsating red giants fainter than the TRGB are a mixture of RGB and AGB giants.

Finally, we compare the Petersen diagrams of the LMC, SMC and Galactic bulge variable red giants and find that they are basically identical indicating that the variable red giants in all these different stellar environments share similar pulsation properties.

**Key words:** Stars: oscillations { Stars: late-type { Stars: AGB and post-AGB { Magellanic Clouds

## 1. Introduction

In recent years a significant progress has been made in studies of pulsations of red giants. The major breakthrough occurred when the large microlensing

---

Based on observations obtained with the 1.3 m Warsaw telescope at the Las Campanas Observatory of the Carnegie Institution of Washington.

surveys data of huge samples of these stars spanning several years and all-sky IR surveys photometry became available.

Discovered years ago near-infrared period-luminosity (PL) relation for Mira-type stars (e.g., Glass and Lloyd Evans 1981) was extended to semi-regular variables by Wood and Sebo (1996) who showed the second sequence in the logP {K diagram of the long period variables (LPV). Subsequently, Wood et al. (1999) analyzing MACHO photometric data of stars in the LMC revolutionized this picture showing five parallel ridges in the PL diagram (denoted as A-E). These results were later confirmed by independent studies based on data originated in various projects: EROS+DENIS (Cioni et al. 2001), MOA (Noda et al. 2002), AGAP EROS+DENIS (Lebzelter, Schultheis and Meltchior 2002).

Kiss and Bedding (2003, 2004) used photometric data from the OGLE-II catalog of variable stars (Zebur et al. 2001) supplemented with K-band photometry from 2MASS survey to analyze variable red giants in the Magellanic Clouds. They discovered separate PL relations of a huge number of variables above and below the tip of the red giant branch (TRGB). They distinguished four ridges in the logP {K plane of the pulsating AGB stars and three sequences of giants fainter than the TRGB. They argued that a substantial fraction of variable giants below the TRGB are in the RGB phase.

Ita et al. (2004) presented basically identical, albeit sharper picture of the K-band PL relation using OGLE-II data and more accurate K-band photometry obtained from their SIRIUS IR survey of the Magellanic Clouds. OGLE-II variable red giants were also analyzed by Groenewegen (2004).

Small amplitude variability of red giants has been known for decades. Stebbins and Huer (1930) surveyed photoelectrically red giants and detected variability of many stars of type M0 and later. They discovered that the cooler the star, the larger the scatter of magnitudes. In recent years this rule was extended to K giants. Edmonds and Gilliland (1996) analyzed HST observations of K giants in the globular cluster 47 Tuc. They found variability with periods of 2-4 days and semi-amplitudes of about 5-15 mmag in K3 and later giants. Other surveys of K giants (Jorissen et al. 1997, Henry et al. 2000) confirmed that microvariability of these stars is a common feature. Tens of Galactic small amplitude red variable stars were monitored in long term monitoring programs by John Percy (e.g., Percy, Wilson and Henry 2001).

Small amplitude red giants were also detected among huge number of variables in the Galactic bulge. Wray, Eyer and Paczynski (2004) analyzed the periodicity of 200 000 objects from the OGLE-II catalog of variable stars in the Galactic bulge (Wozniak et al. 2002). They selected 18,000 stars (calling them OGLE Small Amplitude Red Giants (OSARGs) with periods  $10 < P < 100$  days and I-band amplitudes in the range  $0.005 < A < 0.13$  mag. The variables clearly followed two distinct period-amplitude relations.

The nature of small amplitude pulsations of red giants is still not clear. Two mechanisms are proposed: self-excitations of unstable modes (so called Mira-like pulsations) and convection induced excitation of linearly stable modes (solar-like oscillations). Both possibilities were discussed by Dziembowski et al. (2001) and Christensen-Dalsgaard et al. (2001).

One of the by-products of the OGLE survey is a huge number of variable stars found in the Magellanic Clouds. The main purpose of this paper is to provide possibly most precise characteristics of poorly known type of pulsating stars { OGLE Small Amplitude Red Giants in the Large and Small Magellanic Clouds.

## 2. Observations and Data Reductions

All observations presented in this paper were carried out during the second and the third phases of the OGLE experiment with the 1.3-m Warsaw telescope at Las Campanas Observatory, Chile. The observatory is operated by the Carnegie Institution of Washington. The OGLE-II project started in January 1997. The telescope was equipped with the "first generation" camera with a SITe 2048  $\times$  2048 CCD detector working in drift-scan mode. The pixel size was 24  $\mu$ m giving the 0.417 arcsec/pixel scale. Observations were performed in the "slow" reading mode of the CCD detector with the gain 3.8 e<sup>-</sup>/ADU and readout noise of about 5.4 e<sup>-</sup>. For details of the instrumentation setup of OGLE-II, we refer the reader to Udalski, Kubiak and Szymanski (1997). The OGLE-II fields cover 4.5 square degrees in the central parts of the LMC and 2.4 square degrees in the SMC.

Second phase of the OGLE project was completed in November 2000 and in June 2001 the third stage of the experiment began. The Warsaw telescope was equipped with a "second generation" CCD mosaic camera consisting of eight SITe ST-002a CCD detectors with 2048  $\times$  4096 pixels of 15  $\mu$ m size (Udalski 2003a). This corresponds to 0.26 arcsec/pixel scale and the field of view of the whole mosaic 35<sup>o</sup>  $\times$  35<sup>o</sup>. The last observations presented in this paper were collected in November 2003, so the analyzed data span 8 years.

Photometry was obtained with I and V filters, closely resembling the standard system. For the period analysis I-band observations were used, in which the majority of frames were taken. The OGLE-II photometry was obtained using the Difference Image Analysis (DIA) method { image subtraction algorithm developed by Alard and Lupton (1998) and Alard (2000), and implemented by Wozniak (2000). Contrary to the general catalog of variable stars in the Magellanic Clouds (Zebur et al. 2001), the DIA photometry was reprocessed for all stars found in the reference images of the fields. In this way more complete sample, in particular of very small amplitude variable red giants, could be detected among monitored stars. The OGLE-III photometry comes from the standard OGLE-III photometry pipeline (Udalski 2003a) and is also based on DIA.

We tied photometry obtained during the second and third phases of the OGLE survey by shifting the OGLE-III magnitudes to well calibrated OGLE-II photometry. For each object we determined the median difference between OGLE-III and OGLE-II luminosities of at least several dozen constant stars in the closest neighborhood. This value was then used as the correction of the OGLE-III magnitudes. Combined OGLE-II and OGLE-III datasets with its

much longer time span made it possible to derive much more complete and accurate periodicities by filtering out spurious, non-coherent and unstable frequencies possible in the OGLE-II dataset alone.

Altogether, we collected from about 400 to 800 observations in *I* filter (depending on the field) and about 30-70 measurements in the *V*-band. In the OGLE-II phase the effective exposure time lasted 125 and 174 seconds for the *I* and *V*-band, respectively. OGLE-III exposure time of observations in *I*-band was increased to 180 seconds. The median seeing of our dataset was about 1.03.

In the majority of other analysis of red giant pulsations near infrared photometric bands were used, especially *K*-band magnitudes. Stars in the latest phases of evolution are characterized by the high mass-loss, and they are often obscured by significant amount of dust. Therefore, infrared bands minimize the scatter of the PL sequences caused by interstellar extinction. On the other hand infrared magnitudes usually come from single epoch measurements what increases the scatter.

We used in our analysis reddening free Wesenheit index,  $W_I$ , defined as:

$$W_I = I - 1.55(V - I)$$

where *I* and *V* are intensity mean magnitudes and 1.55 is the mean ratio of total-to-selective absorption ( $A_I = E(V - I)$ ). It is worth noticing that the PL diagrams which use  $W_I$  index present sequences fairly narrow, similar or even better defined than in the  $\log P$  - *K* diagrams.

### 3. Selection of O S A R G s

We searched for variable red giants among *I*-band light curves of all stars brighter than 17 mag and 17.5 mag in the LMC and SMC, respectively. Usually, a search for variable stars is preceded by a preliminary selection based, for instance, on scatter of observations. However, we performed the period analysis of each star, because substantial number of small amplitude variable red giants could have been rejected during the preselection process.

At the first stage of the search we performed a low-resolution period analysis of about 260 000 and 120 000 objects in the LMC and SMC, respectively. We used program *Fnpicks* (Kolaczowski 2003, private communication) which implements the algorithm of Discrete Fourier Transform.

After selection of the highest peak in the power spectrum corresponding to the primary dominant period we examined periodograms with higher resolution and determined more accurate primary periods. Then, the light curve of analyzed object was folded with derived period, approximated by third order Fourier series and fitted functions were subtracted from the observational data. The residuals were again searched for other periodic signal by repeating the procedure. Only periods with the signal-to-noise parameter larger than 3.6 were considered as real. Up to five dominant periods per object were kept. Fi-

nally, all objects with no V-band measurements and stars with colors  $V - I < 1.0$  (e.g., Cepheids, main sequence stars) were rejected.

The input list of stars consisted of both, variable and non-variable, objects. Separation of red giants with the smallest amplitudes from non-variable stars turned out to be quite difficult. In some cases neither the scatter of the measurements, nor signal-to-noise parameter produced by the period searching program, nor even visual inspection of the light curves, allowed to distinguish between variables and non-variables. Therefore, for each object we performed a second periodicity search using another program, *Predator*, (Mizerski 2004, private communication) based on another method of the frequency analysis (Lomb-Scargle algorithm). For further studies we limited our sample to stars which the dominant period derived during the first search was found between 25 highest peaks of the periodogram obtained in the second stage. This method allowed us to reject the vast majority of non-variable objects.

The vast majority of the selected small amplitude variables are multi-periodic. Certainly, a small part of periods derived in stars from our sample might be spurious. This is inevitable when analyzing light curves of variables with so small amplitudes. However, the visual inspection of light curves indicates, that the vast majority of variables have dominant periods well determined, what combined with large number of objects in the final sample enabled us to study statistical features of variable red giants.

Fig. 1. Periodogram diagrams for variable red giants in the LMC. The upper diagrams are constructed using primary periods with  $S/N > 6$ . The lower diagrams show the second and third dominant periods ( $W_1$  relation for giants from the ridge A (left panel) and C (right panel)).

In the upper panels in Fig. 1 we show the PL relation,  $\log P \{W_I\}$ , for our sample of variable red giants in the LMC. Only primary periods with signal-to-noise parameter larger than 6 are presented: altogether 16000 stars. PL diagram showing several clear well separated sequences of pulsating red giants is basically identical with infrared diagram for the K-band (Ita et al. 2004). We labeled the ridges A-D following notation of Wood et al. (1999), adding label  $C^0$  for a clear sequence between C and D, weakly seen in the K-band (Ita et al. 2004). The sequence denoted as  $C^0$  by Ita et al. (2004) is practically merged with the ridge B in Fig. 1.

Lower panels in Fig. 1 show the PL relations constructed using the second and third dominant periods of stars highlighted in magenta in the upper panels, that is the sequence A (3800 objects) in the left diagram, and sequence C (1400 objects) in the right diagram. As can be noticed, both groups of red giants form completely different patterns in the secondary period  $\{W_I\}$  plane. Stars with the primary periods in the sequence A reveal four narrow PL ridges corresponding to the sequences A and B, and additional wider sequence corresponding to the sequence D. Sequences C and  $C^0$  are not present at all in the bottom-left plot in Fig. 1.

On the other hand, stars with the primary periods located in the sequence C also form clear ridges in the bottom-right panel of Fig. 1. They correspond to the sequences B, C and less clearly  $C^0$ . The ridge D is practically not seen in this panel. It is also evident that none of the secondary periods of this group correspond to the sequence A.

This striking difference between variable giants belonging to ridges A and C suggests that both groups represent different types of pulsating stars. The first group is referred in this paper as OSARG. The second group of long period variables (LPV), consisting of semi-regular variables (SRV) and Mira type variables, will be analyzed in a forthcoming paper. It is worth noticing here that in both groups of stars many secondary periodicities are very close to the primary ones (i.e., stars with primary periods in the ridge A or C have other dominant periods in the ridge A or C, respectively, as well) suggesting non-radial pulsations of these objects (see Section 4 and 5).

Sequence B (2500 objects) in the upper panels of Fig. 1 must contain both types of pulsating giants: OSARG and SRV/Mira stars because this ridge is populated in both bottom panels of Fig. 1. To separate these groups we used the second and next (if present) dominant periods. If one of these periods fell into the sequence A, we classified such an object as OSARG. Otherwise, the star was added to the list of SRV/Mira objects.

Left panels in Fig. 2 show properties of OSARGs with the primary periods in the ridge B. Right panels present the same diagrams for SRV/Mira variables. In the top row PL relations of the primary dominant periods are repeated with OSARGs (left) or SRV/Mira stars (right) highlighted in magenta.

In the next row of Fig. 2 PL diagrams for other dominant periods are presented. It is clearly seen that the secondary periods of SRV/Mira objects populate mostly sequences B (its part denoted as  $C^0$  by Ita et al. 2004) and C similar to objects with the primary periods in the ridge C (right panels in Fig. 1).

Fig. 2. The top panels present the primary period $\{W_I$  relation for variable red giants in the LMC (Fig. 1). The next rows show as follows: secondary periods $\{W_I$  relation, period $\{$ amplitude (I-band) relation and period $\{$ color ( $V - I$ ) relation for stars highlighted in magenta in the top panels. Least square fits for period $\{$ amplitude and period $\{$ color relation of stars in the left column are repeated for comparison in appropriate panels of the right column.

On the other hand the secondary periods of stars from the ridge B classified as OSARGs closely follow the pattern of stars with primary periods in the sequence A (left panels in Fig. 1). Thus, we indeed see that the ridge B for primary periods is a mixture of OSARG and SRV/Mira variables (stars with different pulsational properties). Our criterion of classification seems to properly separate stars belonging to both groups.

Fig. 3. Color-magnitude diagram of the LMC red giants. Objects classified as OSARGs are plotted in magenta and SRV/Mira stars in cyan.

The period-amplitude and period-color diagrams for stars with primary period in the ridge B, presented in the consecutive rows in Fig. 2, reveal that though the ranges of the amplitudes and colors of both groups of variables overlap, they follow distinct  $\log P$ - $A$  and  $\log P$ - $(V-I)$  relations. The SRV/Mira objects typically have larger amplitudes and span wider range of colors. All these features also suggest that OSARG and SRV/Mira variables are different types of pulsating stars.

Similar test performed on variable red giants that have the primary periods in the ridge D in Fig. 1 indicates that this group is also a mixture of OSARG and SRV/Mira stars, i.e., the former have dominant periodicities in the ridge A while the latter do not.

Fig. 4. Examples of the light curves of the O SARG objects in the LMC. In the first three upper rows light curves of O SARGs fainter than the TRGB are presented. In the next two rows examples of O SARGs above the TRGB are shown. Bottom two rows present variables with distinct long secondary periods.

Fig. 3 presents the color(magnitude) diagram of the LMC stars. Only the upper part of the red giant branch is shown. Objects classified as O SARG and SRV/Mira are plotted in magenta and cyan, respectively.

Fig. 4 shows eight typical light curves of O SARGs in the LMC. The original data (left panel) and folded light curves (right panel) are arranged according to periods. To compare amplitudes of variability all diagrams have the same magnitude scale. Three upper light curves present typical O SARGs below the TRGB, next two rows show giants brighter than the TRGB, two lowest light curves are examples of stars with long secondary periods (see below).

#### 4. O SARGs above the TRGB

Kiss and Bedding (2003) found a clear drop of stellar density of variable red giants above the TRGB. They also noticed that PL relations of giants brighter and fainter than the TRGB are shifted by about  $\log P \approx 0.05$ . Therefore, we separated our sample of O SARGs into two groups, namely the stars above and below the TRGB and analyzed them separately. Detailed studies of the multi-periodic stars revealed significant differences between both groups. Hereafter we refer O SARGs brighter than the TRGB as type "a" (for "above TRGB") with the sequence number (e.g.,  $a_1$  means the sequence with the longest periods). Objects fainter than the TRGB will be described by letter "b" (for "below TRGB") with the appropriate sequence number.

We used I-band magnitudes of the TRGB determined by Udalski (2000):  $I_{\text{TRGB}} = 14.56$  mag in the LMC, and  $I_{\text{TRGB}} = 14.95$  mag in the SMC to separate the stars. Fig. 5 shows the  $\log P$  vs  $W_I$  PL relation of the O SARGs above the TRGB in the LMC and SMC (about 2000 and 400 objects, respectively). For each star up to four points representing the primary and next three dominant periods are marked. Four distinct sequences, labeled  $a_1$ – $a_4$ , are clearly visible in the PL relations of both galaxies.

Sequence  $a_3$  corresponds to the ridge A of Wood et al. (1999) while sequences  $a_2$  and  $a_1$  were merged in their ridge B (Fig. 1). Poorly populated ridge  $a_4$  has not been noticed in earlier analyses. Sequence  $a_3$  is the most numerous in the LMC and SMC. Primary periods of almost half of the O SARGs of type "a" populate sequence  $a_3$  but for further 40% of stars one of the next dominant periods also corresponds to this sequence. About 20% of primary periods of O SARGs fall into the sequence  $a_2$ , and only a few percents of the variables have the primary periods in the sequences  $a_1$  and  $a_4$ . The remaining O SARGs above the TRGB exhibit the dominant periodicity in the sequence of long secondary periods (LSP).

Fig. 5 indicates that the PL relations for  $W_I$  index of O SARGs brighter than the TRGB are not linear. The slope becomes steeper for brighter  $W_I$  indices. It is worth noticing that the slope of the PL relations is different in the LMC and SMC, namely it is steeper in the LMC than in the SMC.

Fig. 5. Period- $W_I$  diagrams for O SARG stars brighter than the TRGB in the LMC (upper panel) and SMC (lower panel). Up to four dominant periods for each star are plotted.

Fig. 6 presents the Petersen diagram of O SARG stars from the LMC located above the TRGB, that is a diagram where the period ratio of two periods in a multi-period object is plotted against logarithm of the longer period. Period ratios of all combinations of up to four dominant periods in each object were plotted in the top panel of Fig. 6.

Six smaller panels present the Petersen diagrams for objects that possess periods in the four sequences,  $a_1$ – $a_4$ , in the PL diagram. For example, in the left-top panel the ratios of the periods for objects that pulsate simultaneously with periodicities falling into sequence  $a_1$  and  $a_2$  are presented. All combinations of sequences are shown. One can easily find a characteristic period ratio of the sequences and its dependence on period.

It can be noted from Fig. 6 that the considerable fraction of the points

Fig. 6. Petersen diagram for O SARG stars brighter than the TRGB in the LMC. The large panel presents ratios of the four dominant periods of all these stars. The small diagram presents objects pulsating with periods located in the four sequences in the PL diagram (Fig. 5).

in the Petersen diagram is located in the region of period ratios larger than 0.97. Such very closely spaced frequencies were also detected in other types of pulsating stars, e.g., RR Lyr variables (Olech et al. 1999) or Cepheids (Moskalik, Kolaczowski and Mizerski 2003), and were interpreted as an indication of non-radial oscillations. By analogy we suppose that these objects also pulsate non-radially.

The phenomenon of close periodicities is very common in O SARGs. For about 35% of O SARGs in the LMC and 30% in the SMC we found two (or more) close frequencies between five highest peaks in the periodograms. More detailed analysis of the periodograms would probably significantly increase the number of stars oscillating in non-radial modes.

In about 55% of O SARGs long secondary periods (LSP, Houck 1963), i.e., per-

iods typically 5{15 times longer than primary periods, were detected. A clump of points representing these periodicities is clearly visible in the lower-right part of the Petersen diagram. For about half of the stars exhibiting LSP, amplitudes of the long period variability are larger than amplitudes of typical OSARG's pulsation modes (see an example in the bottom panel of Fig. 4). However, the behavior of other periodicities in these stars, like their period ratios, is similar to other OSARGs. Therefore we believe that these objects constitute a common group with typical OSARG stars.

It is worth noticing that LSPs fall into distinct PL sequence in Fig. 5, roughly consistent with the sequence D of Wood et al. (1999). The origin of the LSP phenomenon is still unknown. Possible explanations include "strange" modes of pulsation, rotation of spotted star, episodic dust ejections, or eclipses of giant by a cloud of dust and gas surrounding the orbiting companion. More details concerning LSP objects are presented by Wood, Olivier and Kawaler (2004).

Finally, the Petersen diagram made it possible to measure the typical ratio of periods corresponding to different sequences,  $a_1 - a_4$ , in the PL diagram. We obtained the following average values:

$$\begin{aligned}
 P_2/P_1 &= 0.69 \\
 P_3/P_1 &= 0.50 \quad (P_3/P_1 = 0.13 \log P + 0.74) \\
 P_4/P_2 &= 0.39 \\
 P_3/P_2 &= 0.73 \quad (P_3/P_2 = 0.13 \log P + 0.96) \\
 P_4/P_2 &= 0.56 \\
 P_4/P_3 &= 0.76
 \end{aligned}$$

One can notice that in some cases the period ratio depends on the period. Typically, the longer period, the smaller period ratio. In the case of  $P_3/P_1$  and  $P_3/P_2$  we provide above linear approximations of these relations.

## 5. OSARGs below the TRGB

The nature of pulsating giants below the TRGB is still not clear. Alves et al. (1998) and Wood (2000) argued that all these stars are thermally pulsing AGB stars, while Ita et al. (2002) suggested that substantial fraction of these objects are the first ascent RGB stars. Kiss and Bedding (2003) provided additional arguments supporting this hypothesis. They noted that the PL relations of variables above and below the TRGB show a relative shift of about  $\log P = 0.05$ , what is consistent with the evolutionary temperature difference between AGB and RGB stars with luminosities around the TRGB.

Our analysis of multi-periodic variable red giants provides evidences supporting the hypothesis that below the TRGB both: AGB and RGB pulsating stars are observed. Moreover, we attempted to identify samples of first- and second-ascent red giants fainter than the TRGB.

Fig. 7. Period $\{W_I$  diagrams for OSARG stars fainter than the TRGB in the LMC (upper panel) and SMC (lower panel). Up to four dominant periods for each star are plotted.

OSARGs below the TRGB are much more numerous than variables above the TRGB. Our sample consists of about 13400 stars fainter than the TRGB in the LMC and 2600 such objects in the SMC. Fig. 7 presents the  $\log P \{W_I$  diagram, for this group of stars from the LMC and SMC. Similarly to OSARGs brighter than the TRGB four clear PL ridges labeled from  $b_1$  to  $b_4$ , can be distinguished as well as the sequence of LSPs. The sequences denoted as  $R_1$ ,  $R_2$  and  $R_3$  by Kiss and Bedding (2003) below the TRGB correspond to the sequences  $b_1$ ,  $b_2$  and  $b_3$ , respectively, while the sequences A and B of Ita et al. (2004) correspond to the sequences  $b_3$  and  $b_2$ , respectively.

The  $\log P \{W_I$  relations of OSARGs below the TRGB (Fig. 7) are approximately linear and parallel. The slope of the relation in the SMC is significantly smaller than in the LMC. Using the least square method we fitted the slopes of

5:21 0:05 and 4:15 0:05 for O SARGs of type \b" in the LM C and SM C, respectively. In Table 1 the corresponding zero points of the relation for the sequences  $b_1$   $b_4$  in the  $\log P$   $\{W_I$  plane are listed for the LM C and SM C. For comparison, the zero points of O SARGs brighter than the TRGB fitted with the same slopes for objects with  $W_I > 10$  and  $W_I > 11$  for the LM C and SM C, respectively, are also listed (for brighter stars the slopes become steeper).

T a b l e 1  
Zero points of the  $\log P$   $W_I$  relations

| Red Giants brighter than the TRGB |       |       |       |       |
|-----------------------------------|-------|-------|-------|-------|
| Sequence                          | $a_1$ | $a_2$ | $a_3$ | $a_4$ |
| LM C                              | 20.37 | 19.59 | 18.86 | 18.21 |
| SM C                              | 19.26 | 18.59 | 18.01 | 17.48 |
| Red Giants fainter than the TRGB  |       |       |       |       |
| Sequence                          | $b_1$ | $b_2$ | $b_3$ | $b_4$ |
| LM C                              | 20.65 | 19.91 | 19.07 | {     |
| SM C                              | 19.52 | 18.88 | 18.22 | {     |

In further analysis of properties of O SARGs we limited ourselves to the LM C red giants only, as this sample is the most numerous and the data are most accurate. Fig. 8 presents the  $\log P$   $\{W_I$  diagram for all O SARG objects from Figs. 5 and 7 plotted together. The stars brighter than the TRGB are marked with cyan dots. It is clear from Fig. 8 that the ridges of these stars,  $a_1$   $a_3$ , are shifted in  $\log P$  relative to the corresponding ridges of stars fainter than the TRGB:  $b_1$   $b_3$ , as noted by Kiss and Bedding (2003).

The location of the sequence indexed by 4, that went unnoticed in Kiss and Bedding (2003) and Ita et al. (2004), indicates, however, that the ridge of stars fainter than the TRGB,  $b_4$ , is a straight extension of the sequence  $a_4$  of O SARGs brighter than the TRGB, i.e., AGB stars. Fig. 9 shows the distribution of  $\log P$  after subtraction of the average linear fit for the sequence  $a_1$  (plotted with the broken line in Fig. 8) for the red giants brighter (panel A) and fainter (panel B) than the TRGB. Shifts and coincidence of ridges indexed by 1 { 3 and 4, respectively, are again clearly seen. Therefore we suspect that the stars fainter than the TRGB with one of the dominant periods in the sequence  $b_4$  constitute the same type stars as those in sequence  $a_4$ , i.e., the second ascent AGB red giants.

To verify our hypothesis we closer examined the group of O SARGs fainter than the TRGB with one of the periods located in the sequence  $b_4$ . The four dominant periods of these objects are marked by magenta dots in the PL dia-

Fig. 8. Period( $\log P$ ) diagram for all OSARG stars in the LMC. Cyan dots mark OSARGs brighter than the TRGB (AGB stars), black dots OSARGs fainter than the TRGB (RGB sample). Magenta points show the objects with one of the dominant periods belonging to the shortest period sequence  $b_4$ , i.e., AGB stars fainter than the TRGB. Broken line is the linear fit to the sequence  $a_1$ .

gram (Fig. 8). The distribution of  $\log P$  is also presented in panel C of Fig. 9.

It can be immediately noticed from Figs. 8 and 9 that the dominant periods of red giants from the sequence  $b_4$  form clear three additional ridges in the PL diagram corresponding to those indexed by 1{3. What more important these additional ridges are clearly shifted in  $\log P$  compared to the ridges of the remaining OSARGs fainter than the TRGB (black dots in Fig. 8). On the other hand they coincide perfectly with the ridges  $a_1 - a_3$  of giants brighter than the TRGB, i.e., AGB stars and are the extensions of the AGB stars ridges toward fainter objects. Therefore we believe that the stars possessing the periods in the sequence  $b_4$  are indeed the pulsating red giants on the second ascent.

Fig. 10 shows the Petersen diagram for our group of pulsating AGB giants fainter than the TRGB. The similarities with the diagram of AGB stars brighter than the TRGB presented in Fig. 6 are striking. The period ratio sequences presented in the small panels of Fig. 6 are long-period continuations of the sequences of AGB red giants fainter than the TRGB presented in Fig. 10.

Fig. 9. Distribution of  $\log P$  after subtraction of the  $a_1$  sequence. Panel A: O SARG stars brighter than the TRGB; panel B: All O SARG stars fainter than the TRGB; panel C: AGB sample of O SARG stars fainter than the TRGB; panel D: RGB sample of stars fainter than the TRGB. Vertical dashed lines mark position of sequences  $a_1 - a_4$ .

The black dots in Fig. 8 mark the red giants fainter than the TRGB with the dominant periods populating sequences  $b_1 - b_3$ . We suppose that the vast majority of these stars are the first ascent red giants, i.e., RGB giants (hereafter RGB sample). However, this sample can still be contaminated to some extent by AGB stars. Although we already extracted a group of AGB stars, based on the presence of  $b_4$  sequence periodicity, it cannot be excluded that a number of AGB stars that do not excite this mode of pulsation is still hidden among objects marked by black dots. Unfortunately, the natural width of the PL sequences, accuracy of observations and relatively similar distances in  $\log P$  between sequences indexed by 1-3 of the AGB and RGB stars make separation of additional AGB stars impossible.

On the other hand the contamination of the RGB sample by hidden AGB stars cannot be large. Panel D of Fig. 9 shows the distribution of  $\log P$  of the RGB sample. The expected maxima of the distribution of  $\log P$  of AGB stars

Fig. 10. Petersen diagram for O SARG stars fainter than the TRGB with one of the four dominant periods in the sequence  $b_4$ , i.e., AGB stars below the TRGB.

(marked by vertical lines) are considerably shifted and fall between the maxima of the RGB sample. If the number of AGB stars in the RGB sample were considerable then the minima would be filled and much less pronounced than seen in panel D of Fig. 9. Therefore, we conclude that our RGB sample indeed constitutes in the statistical sense the RGB giants group.

Fig. 11 presents the Petersen diagram of the RGB sample. Similarly to stars located above the TRGB, non-radial pulsations (period ratio close to 1.0) and LSPs (period ratio smaller than 0.2) can be distinguished in Fig. 11 in addition to the clear sequences corresponding to the period ratio of all combinations of periods of sequences  $b_1$ – $b_3$ . PL relation of the LSP is a continuation of the LSP sequence of stars located above the TRGB (cf. Figs. 5 and 7), and overlaps with the sequence D of Wood et al. (1999). Both period ratios { close to 1.0 and LSP } are also present in the Petersen diagram of the AGB stars fainter

Fig. 11. Petersen diagram for OSARG stars fainter than the TRGB with one of the four dominant periods in the sequence  $b_1 - b_3$ , i.e., RGB sample.

than the TRGB (Fig. 10).

A new feature clearly seen in the Petersen diagram in Fig. 11 are the sequences corresponding to the period ratios of about 0.9 and 0.95. These ratios are only observed among objects possessing pulsations in the sequence  $b_3$ . The periodicities responsible for these two features form additional sequences in the PL diagram merged with the ridge of  $b_3$  in Figs. 7 and 8 and, thus, additionally widening it compared to other ridges.

About 2000 stars possessing the period ratios between 0.88 and 0.92, and about 1200 objects with the period ratio in the range 0.93{0.97 were found. It is not clear whether the period ratios of about 0.9 and 0.95 correspond to radial pulsations or they represent non-radial oscillations. Models of pulsating giants by Wood et al. (1999) permit such very close radial modes of pulsations. It should be noted that the weak signatures of these two period ratios are also seen in the Petersen diagram of the AGB sample fainter than the TRGB (Fig. 10). It can indicate that either the latter sample is still somewhat contaminated by RGB stars, or that the pulsations responsible for these period ratios can be excited in both types of giants.

## 6. Discussion

In this paper we presented large sample of pulsating red giants detected during the OGLE-II survey in the Magellanic Clouds. We showed that the sample can be divided into two groups with different pulsating properties. We analyzed here in detail the group of small amplitude pulsating red giants (OSARGs).

We showed that the pulsational properties of the first and second ascent OSARGs are slightly different what made it possible to show empirically that pulsating red giants fainter than the TRGB are a mixture of RGB and AGB objects and to select and extract subsamples of pulsating RGB and AGB stars fainter than the TRGB. Follow up observations of these objects could shed a new light on the differences in mechanisms of pulsation of both groups.

Fig. 12. Petersen diagram for OSARG stars in the SMC. Cyan dots mark OSARG stars brighter than the TRGB, black points mark RGB sample OSARGs and magenta dots OSARGs fainter than the TRGB with one of the four dominant periods in the sequence  $b_4$ , i.e., AGB stars.

Knowing the properties of OSARGs in the LMC, the natural question is whether the same properties of small amplitude pulsating red giants are shared by those in other stellar systems. The most obvious candidate for the test is the SMC. Fig. 12 presents the Petersen diagram for the SMC OSARGs. Cyan dots indicate stars brighter than the TRGB while black dots those fainter than the TRGB. Additionally, the giants from the sequence  $b_4$  are marked by the magenta dots.

It is clear that the Petersen diagram of the SMC red giants closely resembles

that of the LMC objects. The giants from the sequence  $b_4$  form characteristic period ratio sequences coinciding with the similar sequences of type \a" O SARGs, i.e., AGB stars. Therefore, similarly to the LMC we interpret those stars as AGB giants fainter than the TRGB. The sample of these stars in the OGLE-II fields is, however, relatively small. This might be related with different metallicity of both Magellanic Clouds. Certainly much larger samples of these stars will become available when OGLE-III data covering entire SMC are analyzed allowing more precise studies of SMC O SARGs. It is also worth noticing that the slopes of PL relations in the SMC are significantly different making these stars of little use as standard candles.

Another important stellar system to test properties of O SARGs is the Galactic bulge where Wray et al. (2004) discovered thousands of such objects based on the OGLE-II photometry. Unfortunately, the Galactic bulge is much worse region for analyzing the variable red giants using PL relations because large and likely non-standard extinction (Udalski 2003b, Sumi 2004) makes it difficult to obtain accurate intrinsic magnitudes of stars even in the IR bands. Another factor diluting the PL diagrams is a large geometrical depth of the Galactic bulge, i.e., different distances to the Galactic bulge giants.

Fortunately the periods and amplitudes of variable giants are free of these problems. Therefore the Petersen diagram and period-amplitude diagram can be directly compared with similar ones for the LMC objects. It should be, however, noted that the Galactic bulge sample was selected based on data with much shorter time-span (only three years), so that considerable fraction of periods in the Wray et al. (2004) list can be spurious or non-stable. Therefore, one can expect more noise in the Galactic bulge diagrams. One can also expect that because of the distance modulus smaller by about 4 mag than that of the LMC the vast majority of red giants in the OGLE-II Galactic bulge sample are stars fainter than the TRGB. The brighter objects would be saturated in the OGLE-II images.

Fig. 13 presents the Petersen diagram for the Galactic bulge red giants from the Wray et al. (2004) sample. All possible period ratios of the dominant periods of these stars listed by Wray et al. (2004) are plotted. As expected the diagram is much more noisy than the corresponding diagram for the LMC O SARG stars fainter than the TRGB (Figs. 10 and 11). Nevertheless, one can immediately notice striking similarities. The characteristic period ratios in both diagrams are identical.

Because the giants from sequence  $b_4$  cannot be extracted in the Galactic bulge with the PL diagram as in the Magellanic Cloud cases we selected them using the characteristic period ratio between sequences  $b_4$  and  $b_3$  equal to 0.76. This sequence is clearly seen in Fig. 13. Period ratios of all dominant periods of these objects are marked by magenta dots in Fig. 13.

It is striking in Fig. 13 that the selected objects populate the same sequences as the LMC O SARGs from sequence  $b_4$ , i.e., the stars interpreted by us as AGB stars fainter than the TRGB (Fig. 10). The remaining giants populate sequences very similar to those of our RGB sample of LMC giants (Fig. 11). Thus, it seems justified to conclude that the small amplitude pulsating red

Fig. 13. Petersen diagram for O SARG stars in the Galactic bulge (Wray et al. 2004). Magenta dots show position of O SARG stars with period ratios corresponding to the AGB O SARG objects fainter than the TRGB in the Magellanic Clouds. Black dots mark the remaining objects, most likely RGB stars.

giants in the Galactic bulge are also a mixture of both { AGB and RGB red giants and pulsational properties of these stars in the Magellanic Clouds and the Galactic bulge are very similar. Further comparison of properties of samples of these two class of giants from different environments could shed the light on the dependence of red giant pulsation mechanism on metallicity which is different in the Magellanic Clouds and Galactic bulge.

It is also possible to explain the duality in the period{amplitude diagram for small amplitude red giants discovered by Wray et al. (2004) in the Galactic bulge. Group A of Wray's et al. giants (variables with lower amplitudes and shorter periods) consists mainly of the most numerous class of O SARGs { stars in the sequence  $b_3$ . Variables in the sequence  $b_2$  and stars brighter than the TRGB form group B of Wray's et al. giants in the  $\log P$  {  $\log A$  diagram.
