

Fragmentation and Evolution of Molecular Clouds. I: Algorithm and First Results

Hugo Martel^{1,2}, Neal J. Evans II,² and Paul R. Shapiro²

ABSTRACT

We present a series of simulations of the fragmentation of a molecular cloud, leading to the formation of a cluster of protostellar cores. We use Gaussian initial conditions with a power spectrum $P(k) \propto k^{-2}$, assume an isothermal equation of state, and neglect turbulence and magnetic fields. The purpose of these simulations is to address a specific numerical problem called artificial fragmentation, that plagues simulations of cloud fragmentation. We argue that this is a serious problem that needs to be addressed, and that the only reasonable and practical way to address it within the Smoothed Particle Hydrodynamics algorithm (SPH) is to use a relatively new technique called particle splitting.

We performed three simulations, in which we allow $N_{\text{gen}} = 0, 1$, and 2 levels of particle splitting. All simulations start up with 64^3 SPH particles, but their effective resolutions correspond to 64^3 , 128^3 , and 256^3 particles, respectively. The third simulation properly resolves the Jeans mass throughout the entire system, at all times, thus preventing artificial fragmentation.

The high resolution of our simulations results in the formation of a large number of protostellar cores, nearly 3000 for the largest simulation. This greatly exceeds the typical number of cores (~ 60) formed in previous simulations, and enabled us to discover various processes that affect the growth of the cores and the evolution of the cluster.

The evolution of the cloud follows four distinct phases, or regimes. Initially, during the growth regime, the cloud evolves into a network of intersecting filaments. After roughly one dynamical time, core formation starts inside the dense gaseous fragments located at the intersection of the filaments, and to a lesser extent inside the filaments themselves, and the cloud enters the collapse regime. During this regime about 50% of the gas, essentially the gas that started up in overdense regions, is converted into cores. Competitive accretion is the main process that controls the mass evolution of cores, but we discovered that this process occurs locally, within each dense fragment. During the following accretion regime, most of the remaining gas does not form new cores, but rather accretes onto the existing cores. Eventually each gaseous fragment has turned into a subcluster of cores, and these subclusters later merge to form the final cluster. The gas left in the system has become negligible, and the system has reached the N-body regime, in which the dynamics of the cluster is governed by N-body dynamics.

The final mass distribution of cores has a lognormal distribution, whose mean value is resolution-dependent; the distribution shifts down in mass as the resolution improves. The width of the distribution is about 1.5 (e.g., a factor of 30 in the mass), and the low-mass edge of the distribution corresponds to the lowest core mass that the code can resolve. This result differs from previous claims of a relationship between the mean of the distribution and the initial Jeans mass.

1. Introduction

1.1. Clustered Star Formation

An understanding of star formation is pivotal to understanding both the origin of galaxies and the origin of planetary systems. A crucial step in the formation of galaxies is the formation of stars. Intensive archaeology of chemical abundances has uncovered the outline of the star formation history of our own galaxy (e.g., McWilliam 1997), and look-back studies are beginning to provide more direct information about star formation beyond $z = 1$. It now appears that the star formation rate was flat to $z > 3$ (Madau 1999; Smail et al. 2000) or even increasing up to the highest observed redshifts (Lanzetta et al. 2002). At least half the extragalactic background light lies in the far-infrared to submillimeter region (Puget et al. 1996; Hauser et al. 1998), suggesting that half the star formation in the history of the Universe has occurred in dusty regions. Submillimeter galaxies, at a mean $z = 2.3$ (Chapman et al. 2005), are forming stars at prodigious rates (up to 1000 solar masses/year), in dusty, molecule-rich environments (e.g., Barger et al. 1998; Cimatti et al. 1998; Cox et al. 2002). Such objects have now been seen even at $z = 6.4$ (Walter et al. 2004). To understand the nature of this process, we must develop a better understanding of massive star formation in similar environments more amenable to detailed study, the dense regions of molecular clouds in our Galaxy.

In a similar way, the study of the origin of planetary systems rests on a deeper understanding of the role of disks in star formation. It is now clear that disks surround most young stars (Beckwith et al. 1990), and we are beginning to study the properties and evolution of these disks (e.g., Mundt, Looney, & Welch 2000). These studies are fundamental to understanding the frequency and variety of planetary systems that current searches are revealing (e.g., Cumming, Marcy, & Butler 1999; Jorissen, Mayor, & Udry 2001; Marcy et al. 2005).

Over the last two decades, we have made substantial progress in understanding how low-mass stars form in relative isolation. Spurred by the elaboration of an elegant theoretical paradigm, beginning with Shu (1977) and culminating in the influential review by Shu, Adams, & Lizano (1987), observers have developed the capability to test predictions of theoretical models. We have a "standard model" and a number of variations, each of which makes predictions that can be tested by observations. In particular, the form of the density and velocity field in the envelope around the forming protostar differs in the different models, and observers are beginning to be able to distinguish these observationally (see reviews by Evans 1999; Myers, Evans, & Ohashi 2000; Andre, Ward-Thompson, & Barsony 2000). Studies of dust continuum emission with instruments like SCUBA is providing a valuable new probe of the density distribution, while molecular line probes probe the kinematics (e.g., Zhou et al. 1993; Zhou & Evans 1994; Myers, Evans, & Ohashi 2000). In addition, predictions that disks would form on scales of 1–100 AU around forming stars (e.g., Terebey, Shu, & Cassen 1984) have been verified (Beckwith et al. 1990). In the study of low-mass, isolated star formation, theory has clearly revealed the path to the observers.

However, most stars probably form not in isolation, but in clustered environments (Elmegreen 1985; Clarke, Bonnell, & Hillenbrand 1999; Evans 1999; Pudritz & Fiege 1999; Elmegreen et al. 2000; Lada & Lada 2003). Massive stars seem to form exclusively in these environments, but the full spectrum of stars and sub-stellar objects forms in clusters (Lada & Lada 1995). In addition, the bursts of star formation seen in distant galaxies are clearly related to the formation of massive stars in clusters. Consequently, understanding them is crucial to understanding galaxy formation. Disks around forming stars have been seen in clustered environments (e.g., O'Dell & Wen 1994; Strom 1995), but interactions among proximate star/disk systems may affect the mass distribution of these disks (Eisner & Carpenter 2003).

In the area of massive, clustered star formation, extensive observations exist (e.g., Churchwell 1993; Kurtz et al. 2000), but theory is very underdeveloped. We know that the typical conditions in dense regions of high mass are quite different from those in dense regions of low mass (e.g., Plum et al. 1997; Shirley et al. 2003b). The temperatures and densities are higher, and the masses of gas are sufficient to form many stars (up to $10^4 M_\odot$). The linewidths of molecular lines are much greater and deviate from the linewidth-size relations known from lower-mass regions and regions not forming stars (Shirley et al. 2003a). The overall density distribution in these high-mass regions seem well approximated by a power law $n(r) = n_f (r/r_f)^{-p}$, with exponent similar to that of low-mass regions ($p \approx 1.8$) (Shirley et al. 2003b) but densities (n_f) 100 times higher (Evans et al. 2002; Mueller et al. 2002). These wide lines are highly supersonic, and turbulence must play a major role. Some dense regions seem to be more fragmented (Wang et al. 1993; Lada, Evans, & Falgarone 1997), as might be expected if clusters are forming.

In these conditions, direct extension of theories of low mass star formation may run into problems. Recent work on the formation of massive stars delineates the theoretical framework (McKee & Tan 2002, 2003) of formation in turbulent dense regions. This work predicts the overall properties of the regions, but the details of the formation and its observational manifestations remain to be understood. The close proximity of other clumps within the overall dense region will perturb the density and velocity fields around a given clump, making the kinds of tests applied to isolated regions less meaningful (and very difficult observationally). Theories that make detailed predictions of observables are needed. Statistical measures must be compared between theory and observation, rather than any specific realization of a simulation because stochasticity is inevitable. For example, the distribution of clump masses and velocities as a function of time could be predicted and compared to observations. If one can follow the process with sufficient dynamic range, the distribution of clump angular momentum could be used to predict things like the frequency of binaries and disks, if supplemented by more detailed calculations of the subsequent evolution of individual structures once they get small enough that their internal dynamical time becomes less than the interaction time. Indeed, predictions of when that point occurs are needed. Larger scale correlations can be studied, such as the tendency toward alignment of angular momentum vectors or magnetic fields.

A number of simulations of the fragmentation of a molecular cloud to form a cluster have been performed (e.g., Larson 1978; Kato, Lattanzio, & Monaghan 1991; Bonnell et al. 1997; Bromm, Coppi, & Larson 1999; Padoan & Nordlund 2002; Tilley & Pudritz 2004; see the recent review articles by Larson 2003; Mac Low & Klessen 2004). Two research groups have been particularly prominent in recent years. Klessen, Burkert, and their collaborators (Klessen, Burkert, & Bate 1998; Klessen & Burkert 2000, 2001; Klessen, Heitsch, & Mac Low 2000; Klessen 2001a,b; Schmeja & Klessen 2004; Jappsen & Klessen 2004, hereafter collectively KB; Li, Klessen, & Mac Low 2003; Jappsen et al. 2005), have used a Smoothed Particle Hydrodynamics (SPH) code to follow the evolution of a region with many times the Jeans mass. They were able to reproduce the observed distribution of clump masses, but found that bound units developed a steeper distribution, more similar to that of stars. This result meshed nicely with recent observations showing that the densest structures in several clouds also have a steeper mass function for masses above $0.5 M_\odot$ (Motte, Andre, & Neri 1998; Testi & Sargent 1998). Bonnell, Bate, and their collaborators constitute the second group (Bate, Bonnell, & Bromm 2002a,b, 2003; Bate & Bonnell 2005; Dale et al. 2005; Dobbs, Bonnell, & Clark 2005). They also used SPH, but have focused mostly on smaller, denser systems for which the gas is optically thick at high densities and the assumption of isothermality breaks down.

An important issue in such simulations is the phenomenon called artificial fragmentation, which can lead to severe numerical problems. In the next subsection, we describe the approach used by the various groups for dealing with this problem.

1.2. Artificial Fragmentation and the Jeans Criterion

Truelove et al. (1997) and Boss (1998) have shown that a minimum requirement of any grid-based simulation of a fragmenting cloud is that the algorithm can resolve the Jeans mass M_J (we shall refer to this as the Jeans criterion). The maximum mass inside a cell must be smaller than $1/64$ of the Jeans mass in order to prevent a spurious, resolution-dependent effect they called artificial fragmentation. This effect, if present, can invalidate the results of star-formation simulations, by producing initial mass functions and accretion histories that are totally wrong. Bate & Burkert (1997) derived a different, but equivalent criterion for SPH. The total mass contained inside the zone of influence of a particle must be less than about twice the Jeans mass in order to prevent artificial fragmentation. As Klein et al. (1999) pointed out, this requirement poses a serious problem for isothermal simulations performed with SPH. The Jeans mass varies as $M_J \propto T^{3/2} \rho^{-1/2}$. Hence, in isothermal clouds, $M_J \propto \rho^{-1/2}$, so the Jeans mass decreases as collapse proceeds. Since the smoothing lengths h are adjusted in such a way that the mass inside the zone of influence of every particle remains constant, the Jeans mass will eventually be underresolved as the density increases.

There is, however, a physical lower limit to the mass of fragments, simply because the isothermal approximation breaks down at sufficiently high densities. Burkert, Bate, & Bodenheimer (1997), Bate (1998), and Klein et al. (1999) extend their simulations into the high density regime by using a barotropic equation of state, which is isothermal below a certain critical density ρ_2 , and adiabatic above it (the actual equation of state is significantly more complex [see, e.g., Scalco et al. 1998], but the barotropic form is a convenient approximation). In the adiabatic regime, $P \propto \rho^{5/3}$, hence $T \propto \rho^{2/3}$ and therefore $M_J \propto \rho^{-1/2}$. There is therefore a minimum Jeans mass, corresponding to the critical density ρ_2 . As long as the Jeans criterion is satisfied at that density, it will be satisfied in the entire system, at all times.

This still poses a problem. The isothermal approximation is valid for densities up to 10^{10} cm^{-3} (Klessen & Burkert 2000). For a region with mean density 10^2 cm^{-3} , the range of 10^8 in density corresponds to a range of 10^4 in Jeans mass. Since the smallest Jeans mass must contain ~ 100 particles to satisfy the Jeans criterion, the total number of particles in the simulation must be at least 1 million, and this would satisfy the Jeans criterion only marginally.

Klessen, Burkert, and their collaborators do not address the problem of artificial fragmentation. They are aware of the problem, but believe that this problem does not affect their conclusions significantly. Bate, Bonnell, and their collaborators are very concerned with artificial fragmentation. They avoid the problem by simulating low-mass systems ($M \sim 50 M_J$), so that their resolution is sufficiently large to reach the regime where the gas becomes adiabatic. They can then use a barotropic equation of state.

In this paper, we consider an alternative approach that can simulate high-mass systems, in the isothermal regime, while still solving the artificial fragmentation problem. This is achieved by using particle splitting, a relatively new and very promising technique (Kitsionas & Whitworth 2002). The basic idea consists of starting the simulations with a manageable number of SPH particles, and then refining the mass resolution locally in regions where additional resolution is needed to satisfy the Jeans criterion. Original particles are automatically replaced (or "split") by a more finely-spaced set of smaller-mass particles wherever extra resolution is required. This can be seen as the Lagrangian counterpart of the Adaptive Mesh Refinement techniques used in Eulerian, grid-based algorithms. In our implementation of particle splitting, SPH particles split into 8 equal-mass particles when the Jeans criterion is locally violated. For an isothermal gas, this results in a new generation of particle splitting every time the density increases by an additional factor of 64.

1.3. Objectives

The primary goal of this ongoing project is to study the effect of feedback from clustered star formation on the evolution of the ISM. However, the issue of feedback will not be addressed in this first paper, for the following reason: The existence of artificial fragmentation casts a huge shadow over all SPH simulations of cloud fragmentation that assume an isothermal equation of state, raising doubts about the validity of such simulations. We feel that this problem is far too important to be ignored, and must be addressed first, and successfully, before we even consider implementing additional physical processes into the algorithm. Solving the problem of artificial fragmentation is an essential first step. In this paper, we address this problem using a SPH algorithm which combines self-gravity, hydrodynamics, particle splitting, and sink particles. This algorithm is described in §2 below.

The main objectives of this paper are the following:

1. Test the feasibility of particle splitting, and investigate, both analytically and numerically, the interplay between particle splitting, sink particles, and the Jeans criterion. Using particle splitting enables us to start up simulations with a small number of particles for a given resolution. However, the feasibility of this approach depends critically on the efficiency of particle removal by sink formation and accretion onto sinks. If a large number of particles split before the formation and growth of sinks becomes important, the total number of particles in the simulation might become too large to be manageable. It is not obvious a priori that sink formation and growth will remove particles sufficiently rapidly to offset the increase in particle number resulting from splitting. One of the main goals of this paper is to determine if the peak number of particles in such simulations remains manageable.

2. Perform a convergence study. We can ascribe to each simulation with particle splitting an "effective particle number," which is the number of particles a simulation without particle splitting would need to achieve the same resolution in dense regions. The three simulations presented in this paper start with 64^3 particles, and allow for $N_{\text{gen}} = 0, 1$, and 2 generations of particle splitting, respectively. The splitting factor is $f_{\text{split}} = 8$, meaning that when a particle splits, it is replaced by 8 particles, each having $1/8$ of the mass of the parent particle. Hence, the effective particle numbers of the three simulations are 64^3 , 128^3 , and 256^3 , respectively. Since we are using identical initial conditions, these three simulations taken together constitute a convergence study, the largest one ever performed for such simulations.

3. Perform the largest simulation of this kind ever done, in terms of effective number of SPH particles or number of protostellar cores formed. For our largest simulation ($N_{\text{gen}} = 2$), the effective particle number is $256^3 = 16,777,216$, about 33 times the largest number of particles used by KB (500,000). Our smallest simulation ($N_{\text{gen}} = 0$, that is, no particle splitting) uses $64^3 = 262,144$ particles, which is comparable to the largest isothermal simulations of KB. Furthermore, we start the simulations with $N_J = 500$ Jeans masses instead of KB's 222 Jeans masses. As a result, we will form a much larger number of protostellar cores. This has three advantages: First, our determination of the initial mass function of protostellar cores will be more accurate. Second, it will enable us to study the mass assembly history and internal structure of the cluster in more detail. And third, forming a larger number of cores might lead to the discovery of some interesting processes in the evolution of the cluster, that would not occur in a cluster with much fewer cores; as we shall see, this is indeed the case.

2. THE NUMERICAL ALGORITHM

2.1. Basic Equations

The evolution of a self-gravitating gas is described by the conservation equations for mass, momentum, and energy, coupled with the Poisson equation and the equation of state,

$$\frac{\partial}{\partial t} + \mathbf{r} \cdot \nabla (\rho) = 0; \quad (1)$$

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} = -\frac{1}{\rho} \nabla P - \nabla \Phi; \quad (2)$$

$$\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla e = P \nabla \cdot \mathbf{v} + \nabla \cdot \mathbf{F} - \nabla \cdot \mathbf{C}; \quad (3)$$

$$\nabla^2 \Phi = 4\pi G \rho; \quad (4)$$

$$P = f(\rho, e); \quad (5)$$

where ρ is the density, P is the pressure, e is the specific internal energy, $\mathbf{v}$ is the velocity, Φ is the gravitational potential, $\bar{\rho}$ is the mean density, and $\nabla \cdot \mathbf{F}$ and $\nabla \cdot \mathbf{C}$ are the radiative heating and cooling rates, respectively. Equation (4) requires some explanation. To prevent the overall collapse of the cloud, we assume that the cloud is essentially infinite, and use periodic boundary conditions. However, a periodic gravitational potential is only possible if the total mass of the system vanishes. By adding the term $\bar{\rho} \Phi$ in equation (4), the effective mass, defined as the integral of the source term $\rho - \bar{\rho}$ over the computational volume, does vanish, and a periodic solution for Φ becomes possible. A valid interpretation of equation (4) is that the term $\bar{\rho} \Phi$ accounts for whichever process makes the cloud globally stable, while it is the fluctuation $\rho - \bar{\rho}$ that make the cloud locally unstable. Klessen, Heitsch, & Mac Low (2000) and Mac Low & Klessen (2004) have suggested that supersonic turbulence might explain the global stability of clouds.

It is important to realize that equation (4) is still physically correct. Since the cloud is assumed to be infinite, the term $\bar{\rho} \Phi$ represents a uniform, negative density background extending to infinity in all directions, and such component cannot, by symmetry, exert any force in any direction on a mass element. For a more formal description, we refer the reader to Alécian & Léorat (1998), and references therein.

In this paper, the set of equations we are using is significantly simpler. First, since we use Smoothed Particle Hydrodynamics (SPH), a Lagrangian, particle-based algorithm, mass is automatically conserved, and we can ignore the continuity equation (1). Second, we assume that the gas is isothermal. The specific internal energy e is therefore constant in space and time, and equation (3) can be ignored as well. The equation of state, equation (5), becomes

$$P = \frac{c_s^2}{\gamma} \rho; \quad (6)$$

where $c_s(\rho)$ is the sound speed, which is constant in an isothermal gas, and γ is the polytropic constant³.

³The relationships between the concepts of polytropic constant, polytropic equation of state, and isothermality are often reported incorrectly. The polytropic constant γ is the ratio of the specific heat capacities at constant pressure and constant volume. A polytropic equation of state has the form $P/\rho^\gamma = \text{const}$, but such an equation is valid only if the entropy of the gas is constant both in space and time. It is often said that $\gamma = 1$ for an isothermal gas, but this is incorrect in general. In our simulations, $\gamma = 5/3$, the equation of state is not polytropic, and it is the coupling between the gas and a background radiation field that makes the gas isothermal.

{ 7 {

The system of equations (1)-(5) reduces to

$$\frac{dv}{dt} = -\frac{C_s^2}{r} \quad r \quad ; \quad (7)$$

$$r^2 = 4 G (\quad) ; \quad (8)$$

where $d/dt = \partial/\partial t + \mathbf{v} \cdot \nabla$ is the Lagrangian time derivative.

2.2. The SPH=P³M Algorithm

We use a hybrid gravity/hydrodynamics algorithm. The gravitational forces are computed using a P³M algorithm (Hockney & Eastwood 1981), while the gasdynamic equations are solved using the SPH algorithm (see Monaghan 1992, and references therein). This hybrid algorithm was originally introduced by Evrard (1988), though we have developed our own version. Our code is actually an Adaptive SPH (ASPH) code (Shapiro et al. 1996; Owen et al. 1998). The ASPH algorithm uses anisotropic smoothing kernels, and a special treatment of artificial viscosity that prevents spurious preheating of low-density regions. However, in this paper, we consider an isothermal equation of state, so preheating is not an issue. We decided to use isotropic smoothing kernels for now (that is, using the Adaptive SPH code as a standard SPH code). We will consider anisotropic smoothing kernels in future work.

We have modified our original algorithm to include a treatment of particle splitting and sink particles. The implementation of these features is described below.

2.3. Particle Splitting

We have modified our original SPH algorithm to include particle splitting and sink particles. Particle splitting is implemented as follows. We assume that there is a minimum number of particles $n_{J, \text{split}}$ that a Jeans mass must contain in order to be properly resolved and not undergo artificial fragmentation. This gives us the Jeans criterion. Each particle i is required to satisfy the condition

$$\frac{M_J(\mathbf{r}_i)}{m_i} \geq n_{J, \text{split}} ; \quad (9)$$

where M_J is the Jeans mass, which is a function of the density and specific internal energy, $M_J(\mathbf{r}_i)$ is the value of M_J evaluated at the location of particle i (see §4.3 below), and m_i is the mass of particle i . When this condition is violated, the algorithm responds by splitting particle i into f_{split} particles of mass $m = m_i/f_{\text{split}}$. These new particles might themselves be split later as M_J keeps decreasing. For instance, in the case of an isothermal calculation ($\gamma = \text{const}$), $M_J \propto \rho^{-1/2}$, and there is a series of particular densities $\rho = a, a, a, a, \dots$ ($a = \text{const}$) at which particle splitting will occur.

When a particle is split, the algorithm must determine the positions, velocities, masses, and smoothing lengths of the daughter particles⁴. In the original approach of Kitsionas & Whitworth (2002), particles are split into a sphere of 13 daughter particles forming a compact lattice. We use a different approach, in which

⁴ and also the specific internal energies, if the gas is not isothermal.

{ 8 {

particles are split into $f_{\text{split}} = 8$ particles located on the vertices of a cube. This approach will be easier to generalize to Adaptive SPH later. We create the daughter particles as follows: Consider a particle i , with position $\mathbf{r}_i$, velocity $\mathbf{v}_i$, mass m_i , and smoothing length h_i , that violates the condition (9), and therefore needs to be split. If $(r)_i$ is the mean particle spacing in the vicinity of particle i , the 8 daughter particles will be located at

$$\mathbf{r} = \mathbf{r}_i + \frac{(r)_i}{4} \begin{pmatrix} 2 & 3 \\ 1 & 15 \\ 1 & 1 \end{pmatrix}; \quad (10)$$

so that the spacing between daughter particles will be $(r)_i = 2$.⁵ In the initial conditions, the smoothing lengths h_i of the particles are initialized to be a multiple of the mean particle spacing: $h_{i,\text{init}} = \lambda_2 r$, where λ_2 is a constant (using the notation of Shapiro et al. 1996). Then, as the calculation proceeds, the algorithm evolves the smoothing lengths h_i in such a way that this relation is (roughly) maintained locally. Hence, the local particle spacing can be estimated using $(r)_i = h_i / \lambda_2$. Equation (10) reduces to

$$\mathbf{r} = \mathbf{r}_i + \frac{h_i}{4\lambda_2} \begin{pmatrix} 2 & 3 \\ 1 & 15 \\ 1 & 1 \end{pmatrix}; \quad (11)$$

In our simulations, we generated initial conditions using $\lambda_2 = 2$, to provide a sufficient number of neighbors.

We set the velocity of the daughter particles equal to $\mathbf{v}_i$. We could use a more sophisticated approach that would take the local velocity gradient into account, but this is not really necessary. Particles tend to readjust themselves in one time step, erasing any velocity fluctuation at scales smaller than the smoothing length. Finally, we set the masses of the daughter particles equal to $m_i/8$, and their smoothing lengths equal to $h_i/2$.

2.4. Sink Particles

Sink particles must be used in simulations of cloud fragmentation to reduce the time steps, if we hope to determine the initial mass fraction of collapsed fragments. It is not sufficient to use an algorithm with individual time steps, because as the gas fragments and collapses, most SPH gas particles end up in dense regions with short dynamical times. By replacing each dense clump of gas particles by a single object, called a sink particle (Bate, Bonnell, & Price 1995; Bromm, Coppi, & Larson 2002), we can eliminate this problem and increase the speed of the algorithm tremendously. In our implementation of sink particles, we use the method of Bate, Bonnell, & Price (1995), and we refer the reader to that paper for details.

2.4.1. Creation of Sinks

Our algorithm uses individual time steps. Each particle i is given a time step $t_i = (t)_{\text{basic}} 2^n$, where $(t)_{\text{basic}}$ is the "basic time step," and n identifies the time step bin where the particle belongs. Sink particles are created only at the end of the basic time steps, when all the particles are in sync. This greatly simplifies

⁵Note: because of the periodic boundary conditions, some daughter particles are wrapped around the computational box if particle i is located less than $(r)_i/4$ away from the edge of the box.

the implementation. Gas particles are replaced by sinks when they reach a threshold density ρ_c . This density threshold is a numerical parameter that does not have any physical meaning, except for the fact that the assumption of isothermality must be physically valid at all densities below ρ_c . The smallest collapsed objects that can form in the simulations will have a mass equal to $(M_J)_c$ the Jeans mass at the density ρ_c . Hence, ρ_c fixes the mass resolution of the algorithm, much in the same way as the softening length fixes its length resolution.

To create sinks, the algorithm identifies all particles whose density⁶ exceeds the threshold density ρ_c for sink creation. These particles are then sorted in decreasing order of the density. Starting with the densest particle, the algorithm finds all n_{acc} particles within a fixed radius r_{acc} of that densest particle, where r_{acc} is called the accretion radius. An important issue is how to determine the appropriate value for r_{acc} , or equivalently, how many particles n_{acc} should be turned into a sink. We shall assume that it takes a minimum number of particles, $n_{J,\text{min}}$, to properly resolve a Jeans mass, and we will set that number equal to the number of particles $n_{J,\text{aff}}$ that a Jeans mass must contain to prevent artificial fragmentation. This makes sense, since the negative consequence of underresolving the Jeans mass is precisely to cause artificial fragmentation. The number of particles n_{acc} must also exceed the number of particles $(n_J)_c$ inside a Jeans mass at the threshold density ρ_c , otherwise sub-Jeans mass objects would be turned into sinks. Hence, the condition is

$$n_{\text{acc}} = \max [n_{J,\text{min}}; (n_J)_c] : \quad (12)$$

This ensures that every fragment replaced by a sink particle (i) is properly resolved, and (ii) contains at least a Jeans mass. We adjust r_{acc} such that $n_{\text{acc}} = \max [n_{J,\text{min}}; (n_J)_c]$ at the threshold density ρ_c . If the values of n_{acc} are systematically smaller than $\max [n_{J,\text{min}}; (n_J)_c]$, this would imply that we chose a value of r_{acc} that was too small, and sinks would then form at densities much larger than ρ_c . Conversely, if the values of n_{acc} are systematically larger than $\max [n_{J,\text{min}}; (n_J)_c]$, this would indicate a value of r_{acc} that was too large, effectively reducing the mass resolution of the algorithm, by forming objects that are too massive. The actual determination of r_{acc} is described below.

To create a sink particle, a second condition must be satisfied,

$$\frac{E_{\text{th}}}{E_{\text{gr}}} < 1; \quad (13)$$

where E_{th} and E_{gr} are the thermal and gravitational energies of the particles inside the accretion radius, respectively. Bate, Bonnell, & Price (1995) use < 0.5 as a criterion. However, using equation (13) is more consistent with the fact that we are trying to turn Jeans-mass clumps into sinks, since by definition $\beta = 1$ for a uniform sphere of mass $M = M_J$. If both conditions are satisfied, the particles inside r_{acc} are removed and replaced by a sink particle, which inherits the properties of the parent particles (center of mass position and velocity, total mass, and total angular momentum). The algorithm then selects the next densest particle still available (some particles with $> \rho_c$ might have been incorporated into sinks created around denser particles), and the process is repeated until all particles with $> \rho_c$ have been considered.

⁶We use the expression "density of a particle" for convenience; strictly speaking, SPH particles do not carry a density, hence the correct expression is "the density of the gas at the location of a particle."

2.4.2. Mass Evolution of Sinks

Two physical processes can increase the mass of protostellar cores: mergers with other cores, and accretion of gas by cores. In the algorithm, these processes correspond to merging of sinks, and accretion of SPH gas particles by sinks, respectively.

The merging of sinks is an interesting issue. Allowing sinks to merge would clearly affect the final mass distribution of protostellar cores. Unfortunately, no known prescription exists for implementing sink merging into a SPH algorithm. We intend to investigate this issue in a separate paper, but for now we will make the usual assumption that sink particles do not merge, as in Bate, Bonnell, & Price (1995), KB, and others.

Accretion of gas particles onto sinks is also performed at the end of each basic timestep. The algorithm checks for gas particles that are located inside the accretion radius r_{acc} of a sink particle. These particles are then accreted by the sinks, and the sink properties (position, velocity, mass, angular momentum) are updated accordingly. If a gas particle is within the accretion radius of several sinks, we compute the total energy of the (particle + sink) systems, and choose the sink for which this energy is the smallest. Unlike Bate, Bonnell, & Price (1995), we do not require that the energy be negative. Such a criterion would fail in general, because in these simulations the gas tends to fall onto sinks at supersonic speeds that exceed the escape velocity from the sink. This happens when gas particles are accelerated by large mass concentrations, that might contain several sinks. A gas particle approaching a cluster of sinks will be accelerated by the whole cluster, and will acquire a velocity comparable to the escape velocity from the whole cluster. But this velocity will always exceed the escape velocity from the particular sink that will accrete that particle. Hence, the gas particle will not be gravitationally bound to the sink onto which it accretes. This is not a concern, because the physical process responsible for the final stage of accretion is not gravitational capture, but rather physical collision between a gas particle and a sink. In a simulation without sinks, a gas particle approaching a dense clump at supersonic speed would be decelerated down to subsonic speeds by the artificial viscosity, resulting in the conversion of kinetic energy into thermal energy, that would then be radiated away since the gas is assumed to be isothermal. But this process would occur at scales smaller than r_{acc} , and therefore cannot occur when clumps are being replaced by sinks. By allowing large-velocity particles to accrete onto sinks, we are essentially putting in the subgrid physics of collision, viscous deceleration, and radiative dissipation by clumps smaller than r_{acc} .

When using sinks, boundary conditions must be applied at the accretion radius r_{acc} , otherwise the SPH calculation of the density, pressure forces, and viscous forces on gas particles located immediately outside r_{acc} would be incorrect, resulting in spurious effects. This is discussed in great detail in Bate, Bonnell, & Price (1995), and also in Bromm, Coppi, & Larson (2002). Our implementation of boundary conditions follows the description of Bate, Bonnell, & Price (1995). Interestingly, in our simulations, the effect of boundary conditions turns out to be quite small. We found that most gas particles fall radially toward sinks, and collide with them at supersonic speeds. As Bate, Bonnell, & Price (1995) point out, viscous boundary conditions have a negligible effect for particles falling radially, while pressure boundary conditions have a negligible effect for particles moving supersonically. Our findings are consistent with that claim.

3. CLOUD FRAGMENTATION

In this section, we discuss some aspects of the numerical simulations of cloud fragmentation, including the interplay between resolution, artificial fragmentation, particle splitting, and sink pyarticles. For the sake of the discussion, we consider a particular simulation of KB, which we call the "benchmark simulation." For

this particular simulation, the number of particles is $N = 200,000$, the initial number of Jeans masses is $N_J = 222$, the mean density, in computational units, is $\rho = 1/8$, and the threshold density for creating sinks is $\rho_c = 40,000$. For the number of particles necessary to prevent artificial fragmentation, we assume $n_{J,aff} = 100$ (this is a guess; no value of $n_{J,aff}$ is provided by KB). Notice that this is one of the highest-resolution simulation performed by KB. They have performed a higher-resolution simulation with $N = 500,000$, and by lowering the threshold density and the initial number of Jeans masses, they were able to increase their mass resolution significantly. Because of the reduced number of Jeans masses in this simulation, the more suitable calculation for us to use as a benchmark is the one with $N = 200,000$.

3.1. Mass Resolution

We can estimate the effect of particle splitting on the mass resolution of the algorithm using a simple calculation. We assume that the system has a total mass M_{tot} , and the simulation starts up with N equal-mass particles of mass $m = M_{tot}/N$. Because the initial density fluctuations are small (δ_{init}), and the gas is isothermal, the initial Jeans mass $M_{J,init}$ is essentially constant in space. The initial number of Jeans masses in the system is then given by $N_J = M_{tot}/M_{J,init}$, and the initial number of particles in each Jeans mass is given by $n_{J,init} = N/N_J = M_{J,init}/m$.

In the initial state, the system must satisfy the following conditions:

$$n_J > n_{J,aff}; \quad (14)$$

$$\delta < \delta_c; \quad (15)$$

The first condition states that the Jeans mass is properly resolved initially, thus preventing immediate artificial fragmentation, while the second one states that the initial density fluctuations are too small to immediately trigger the formation of sink particles. As the system evolves, the density increases in some regions, and since $n_J \propto M_J^{-1/2}$ for an isothermal gas, n_J decreases in the same regions. Eventually the conditions (14) and (15) will both be violated in dense regions. If condition (15) is violated first, a sink particle will be created, and this will prevent artificial fragmentation from happening. If instead the condition (14) is violated first, then artificial fragmentation will occur, but as long as the fragments remain close to one another, they might eventually get lumped together into a single sink particle once that sink is created. The creation of a sink particle requires an increase in density by a factor $f_{sink} = \rho_c / \rho$, while violating the Jeans criterion requires an increase in density by a factor $f_{aff} = (n_{J,init}/n_{J,aff})^2 = (N/N_J n_{J,aff})^2$. For the benchmark simulation, we get $f_{sink} = 40,000$ and $f_{aff} = 81$. Hence, the Jeans criterion will be violated after an increase in density by a factor of 81, long before sink particles are created. Artificial fragmentation must be prevalent in the isothermal simulations of KB, but these fragments might get re-aggregated when sink particles are created.⁷

There are four possible solutions to the problem of artificial fragmentation. The most obvious solution (1) consists of reducing ρ_c down to 81 or less, so that fragments would turn into sink particles before they are dense enough to experience artificial fragmentation. The obvious drawback of this approach is that the simulation would completely miss the late-stage evolution of dense fragments. If we keep the threshold density at a value $\rho_c = 40,000$, we must then find a way to increase the number of particles per Jeans

⁷Actually, the limited resolution of the gravity solver might help to prevent artificial fragmentation in the simulations of KB (Klessen 2002).

mass. We could (2) increase the initial Jeans mass $M_{J;init}$ by a factor of $(40,000/81)^{1/2} \approx 22$, so that by the time the density reaches ρ_c , the Jeans mass would still contain enough particles to be properly resolved. However, for a fixed initial number N of particles, this would reduce the initial number of Jeans masses in the system from $N_J = 222$ down to $N_J = 10$, leading to poor statistics, as very few cores would form.

If we keep both ρ_c and N_J fixed, we must then reduce the particle mass by a factor of at least $(40,000/81)^{1/2}$ to insure sufficient resolution. If (3) this is done over the entire computational volume, the number of particles would then increase from 200,000 to 4,400,000. This is clearly a brute-force approach, that would result in a tremendous increase in computational time. The better approach (4) consists of reducing the particle mass locally, in dense regions where the Jeans mass is small. This solution can be achieved dynamically, using particle splitting.

After splitting, the mass per particle is given by

$$m = m_{init} f_{split}^{N_{gen}}; \quad (16)$$

where $m_{init} = M_{tot}/N$ is the initial mass of the particles, f_{split} is the splitting factor, and N_{gen} is the maximum number of "generations," that is, the maximum number of splittings a particle can experience. At the threshold density $\rho = \rho_c$, the Jeans mass is given by

$$(M_J)_c = M_{J;init} \frac{1}{\rho_c}^{1/2} = \frac{N m_{init}}{N_J} \frac{1}{\rho_c}^{1/2}; \quad (17)$$

We eliminate m_{init} in equation (17) using equation (16). The Jeans criterion, $(M_J)_c = m_{J;aff}$, becomes

$$\frac{N}{N_J} \frac{1}{\rho_c}^{1/2} f_{split}^{N_{gen}} = m_{J;aff}; \quad (18)$$

This relates the initial number of Jeans masses N_J to the number of splitting generations N_{gen} necessary to prevent artificial fragmentation. This expression is useful for generating initial conditions (see §4.2 below).

3.2. Scenarios

The evolution and fragmentation of the cloud can follow three different paths, which we call scenarios. The particular scenario followed is determined by two parameters: the maximum number of splitting generations N_{gen} and the accretion radius r_{acc} , which determines, among other things, the number of gas particles that are lumped together when a sink is created. Figure 1 illustrates the three different scenarios. Consider first a simulation with an insufficient number of splitting generations, or no splitting at all (N_{gen} too small). As the system evolves, the density increases and the Jeans mass decreases in overdense regions. Eventually, the cloud fragments into Jeans-mass clumps, which themselves fragment as the density increases and M_J decreases, until the density reaches $\rho_{aff} = \rho_{aff}$. At that point, artificial fragmentation occurs, leading to fragments of mass $M < M_J$. As ρ increases and M_J decreases, the mass of these "artificial fragments" might eventually end up above M_J , but further artificial fragmentation will occur, bringing the mass per fragment below M_J again. Finally, when the density reaches the threshold value ρ_c , sink particles are created. KB suggest setting the accretion radius r_{acc} equal to the Jeans length $(R_J)_c$ at the density $\rho = \rho_c$. Each sink particle will then contain about one Jeans mass, implying that several sub-Jeans-mass fragments will be

Fig. 1. Schematic illustration of the various scenarios. Open circles represent fragments composed of SPH particles. Solid dots represent sink particles. From left to right, time increases, local density increases, and Jeans mass decreases.

lumped together into the same sink particle, possibly nullifying the effects of artificial fragmentation. This is Scenario I.

One concern with this scenario is that the Jeans mass $(M_J)_c$ at the threshold density ρ_c might be greatly underresolved (whether or not artificial fragmentation occurred), and replacing it by a sink particle might be inappropriate. For instance, the benchmark simulation of KB contains 200,000 particles and starts up with 222 Jeans masses, or $n_{J,init} = 901$ particles per Jeans mass. The creation of sink particles requires an increase in density by a factor of 40,000, corresponding to a decrease in Jeans mass by a factor $40,000^{1/2} = 200$. Hence, by the time sinks are created, the Jeans mass is down to $901/200 \approx 5$ particles, which is clearly insufficient to resolve it.

Scenario II also describes simulations without particle splitting, or with an insufficient number of splitting generations, but differs from Scenario I in the choice of the accretion radius r_{acc} . In this scenario, r_{acc} is set to a value larger than $(R_J)_c$, by requiring that each sink particle must be made of at least $n_{J,min}$ particles,

as described in §2.4. As a result, fewer sink particles are created, and their initial masses (that is, before they grow by accretion) exceed the Jeans mass by a factor $n_{J,\text{min}} = (n_J)_c$.

Finally, Scenario III describes simulations with a sufficient number of splitting generations. Particle splitting prevents artificial fragmentation, and when sink particles are created, each Jeans-mass fragment contains enough particles to be replaced by a sink particle, without lumping fragments together. The number of sink particles formed under Scenarios I and III should be comparable, since each sink particle is created with a mass $M = (M_J)_c$. However, in Scenario III, the Jeans mass was fully resolved throughout the entire calculation, thus preventing artificial fragmentation, while in Scenario I, artificial fragmentation leads to sub-Jeans-mass fragments, which presumably get lumped together when sinks are created.

Notice that Scenario III is the only one we regard as satisfactory. Scenarios I and II suffer from artificial fragmentation. Also, in Scenario I underresolved fragments are turned into sinks, while in Scenario II Jeans-mass objects ($M < M_J$) are not allowed to form.

4. THE SIMULATIONS

4.1. Initial Conditions

Our method for generating initial conditions is similar to the one used by KB, and is based on the Zel'dovich approximation commonly used for cosmological simulations. We assume that the initial density is described by a Gaussian random field with a density power spectrum $P(k)$, where k is the wavenumber. The details are given in Appendix A. As in KB, we initially consider a power spectrum that follows a power law, $P(k) \propto k^{-n}$, with $n = 2$. The rms density fluctuation at scale $\ell = k^{-1}$ is given by $\sigma^2 = k^3 P^{-1/2}(k)$. Hence, the density fluctuations are larger at smaller scales.

4.2. Numerical Parameters

For all simulations presented in this paper, we use $N = 64^3 = 262,144$, $n_{J,\text{min}} = n_{J,\text{final}} = 100$, $c_s = 40,000$, and $f_{\text{split}} = 8$. We allow up to 2 generations of particle splitting. With $N_{\text{gen}} = 2$, equation (18) gives $N_J = 839$ to be the maximum number of Jeans masses the system can contain initially. This is a rather large number, and it might be desirable to use a smaller one to increase the resolution per fragment, while retaining good statistics. We shall use instead $N_J = 500$ in all simulations. The initial number of particles per Jeans mass is then $n_{J,\text{init}} = N/N_J = 524$. We performed three simulations, Runs A, B, and C, with identical initial conditions and $N_{\text{gen}} = 0, 1$, and 2, respectively, as indicated in Table 1. All other input parameters, including c_s , are the same for all runs, but the accretion radius r_{acc} is adjusted such

Table 1. Numerical Parameters of the Calculations

Run	N_{gen}	$(n_J)_c$	$n_{J,\text{min}}$	n_{acc}	$(N_J)_{\text{sink}}$	$r_{\text{acc}} = L_{\text{box}}$	$r_{\text{min}} = x$	Scenario
A	0	3	100	100	38.1	0.00132	0.30	II
B	1	21	100	100	4.8	0.00066	0.16	II
C	2	168	100	168	1.0	0.00039	0.10	III

Fig. 2. Evolution of the number of particle per Jeans mass, n_J , as the density increases, for three different values of N_{gen} , 0 (no splitting), 1, and 2, as indicated. The horizontal dotted line indicates $n_{J,\text{a.f.}}$, the minimum value of n_J required to prevent artificial fragmentation. Particle splitting, when allowed, occurs when n_J drops below $n_{J,\text{a.f.}}$, and causes n_J to increase by a factor of $f_{\text{split}} = 8$. The vertical dotted line indicates the threshold density $\rho = \rho_c$ for creating sink particles. The solid dots on that line indicate the number of particles that end up inside each sink particle at the time of its creation, according to the various Scenarios (I, II, and III).

that the sinks, at the time of their creation, contain at least 1 Jeans mass, and at least enough particles to be properly resolved (that is, $n_{\text{acc}} = \max[(n_J)_c; n_{J,\text{min}}]$). With this particular choice, Runs A and B, which do not have enough generations of particle splitting, will follow Scenario II; Run C, with ($N_{\text{gen}} = 2$), will follow Scenario III.

Figure 2 shows the evolution of the number n_J of particles per Jeans mass as the density increases. This number decreases as $\rho^{-1/2}$, and drops below $n_{J,\text{a.f.}} = 100$ when the density reaches $\rho = (524=100)^2 = 27.5$. Without particle splitting ($N_{\text{gen}} = 0$), n_J will drop down to $(n_J)_c = 3$ when the density reaches $\rho = \rho_c$. The accretion radius r_{acc} is set to a value larger than $(R_J)_c$, such that groups of $n_{J,\text{min}} = 100$ particles will be converted into sink particles of mass $M_{\text{sink}} = 38M_J$. With $N_{\text{gen}} = 1$, particles will split once their density reaches $\rho = 27.5$ (first star in Fig. 2), increasing n_J from 100 to 800. Then, n_J will keep dropping as increases, reaching $(n_J)_c = 21$ at $\rho = \rho_c$. Groups of 100 particles will then be converted into sink particles of mass $M_{\text{sink}} = 4.8M_J$. Finally, with $N_{\text{gen}} = 2$, particles will split a second time when the density reaches $\rho = 1759$ (second star in Fig. 2), increasing n_J to 800 again. Eventually, n_J will drop to $(n_J)_c = 168$ when the density reaches $\rho = \rho_c$ and groups of 168 particles will be converted into sink particles of mass $M_{\text{sink}} = M_J$. Hence, in a simulation with a sufficient number of splitting generations, the number of particles n_J in a Jeans mass follows a seesaw pattern, always staying above $n_{J,\text{a.f.}}$ and thus preventing artificial fragmentation; Jeans masses are always properly resolved.

The accretion radius r_{acc} must be determined experimentally. We ran the code with various values of r_{acc} , up to the point when a few sinks (20 or so) have formed. We then check how many gas particles were removed when each sink was created. There is an "optimal" number of particles, which is the maximum of $(n_J)_c$ and $n_{J,\text{min}}$ (100 for Runs A and B; 168 for Run C). If the number of particles exceeded significantly that optimal number, this indicated that r_{acc} was too large. We would then try with a smaller value, and iterate until the number of particles turned into each sink was close to the optimal number. Notice that it could not be smaller, because the code would then delay the formation of sinks until enough particles have fallen inside r_{acc} .

Once r_{acc} is determined, we must ensure that the resolution of the algorithm is sufficient to resolve that length scale. For the hydrodynamics, this is achieved by allowing the smoothing length of the SPH particles to shrink down to values smaller than r_{acc} in dense regions. For the gravity, the particle-mesh part of the P³M algorithm uses a 128^3 grid to calculate the gravitational force. The corresponding length resolution is about $2 \times 0.016 L_{\text{box}}$, where $x = L_{\text{box}}/128$ is the cell size. The short-range correction part of the algorithm extends the resolution below the cell size, and the softening length r_{min} can be chosen arbitrarily. We choose r_{min} to be slightly smaller than r_{acc} . With these particular choices, the gravitational force will be properly resolved at all scales down to the scale corresponding to sink formation. The hydrodynamical forces will also be properly resolved, as long as the smoothing lengths shrink down to a value comparable to r_{min} or less. This will happen only if the mass resolution is large enough, that is, a Jeans mass contains at least $n_{J,\text{eff}}$. If this is not the case, however, the hydrodynamical forces will be underresolved, and this is precisely what causes artificial fragmentation.

In low density regions where the smoothing lengths h are much larger, there is clearly a mismatch between the resolutions of the gravity and the pressure force. This should not matter much, since particles are widely separated in these regions, and both gravitational and pressure forces are properly resolved at that scale. We have not observed any artificial clumping of SPH particles in low density regions resulting from the gravity being overresolved compared to the hydrodynamics (see Fig. 5 below).

Table 1 lists the values of $(n_J)_c$, $n_{J,\text{min}}$, n_{acc} , r_{acc} , r_{min} , and the number $(N_J)_{\text{sink}} = n_{\text{acc}} = (n_J)_c$ of Jeans masses inside sink particles at the time of their creation. Notice that the simulation with $N_{\text{gen}} = 2$ is the only one that forms Jeans-mass objects [$(N_J)_{\text{sink}} = 1$].

4.3. Computational and Physical Units

The calculations are performed in computational units. In these units, the total mass M_{tot} of the system, the box size L_{box} , and the gravitational constant G are unity. Hence, the mean density is also unity, and time is expressed in units of $(G)^{-1/2}$. The initial Jeans mass is given by

$$M_{J;\text{init}} = \frac{5kT}{2G}^{3/2} \frac{4}{3}^{1/2} \quad (19)$$

where k is the Boltzmann constant, and is the mean mass per molecule (Tohline 1982). In computational units, this reduces to

$$M_{J;\text{init}} = \frac{5}{3}^{3/2} \frac{3}{4}^{1/2} = 1.0513^{3/2}; \quad (20)$$

{ 17 {

where $\beta = 3kT/2$ for a gas with $\gamma = 5/3$. Since $M_{J,init} = M_{tot}/N_J = 1/N_J$, this reduces to

$$= 0.9672 N_J^{2/3} : \quad (21)$$

This is the prescription for choosing the initial value of β , which then remains constant throughout the calculation under the assumption of isothermality. With our particular choice of $N_J = 500$, we get $\beta = 0.01535$.

The Jeans criterion is given by

$$\frac{M_J}{m} \leq n_{J,eff} : \quad (22)$$

We set $M_J = M_{J,init} (\beta)^{1/2} = M_{J,init}^{1/2}$, and eliminate $M_{J,init}$ using equation (20). We get

$$\frac{\beta^3}{m^2} \leq \frac{36}{125} n_{J,eff}^2 : \quad (23)$$

Whenever the internal energy, density, and mass of a particle violate this condition, that particle is split by the algorithm (unless this would exceed the maximum number of splitting generations N_{gen} allowed).

The simulations are scale-free, and can be rescaled to any physical size of interest. To rescale to physical units, we choose particular values for the temperature T and mean density ρ of the cloud, and compute the initial Jeans mass $M_{J,init}$ using equation (19). The total mass of the system is then $M_{tot} = N_J M_{J,init}$, where N_J was the value used in equation (21) to set the initial conditions, the size of the box is $L_{box} = (M_{tot}/\rho)^{1/3}$, and the physical time is obtained by multiplying the computational time by $(G\rho)^{-1/2}$. This will be illustrated in §7 below, where we rescale the results of our simulations to several physical densities and compare to particular physical systems of interest.

5. RESULTS

Notation in this field is not standardized. For this paper, we adopt the following terminology, partly to facilitate comparison to the work of KB. A "dense region" is a part of a molecular cloud that is likely to form stars; for this paper, we focus on massive, dense regions able to form clusters. A "clump" is a region of enhanced density in the original dense region. A "core" is a clump that has become gravitationally unstable. We will later identify cores with sink particles, and we will interpret the mass function of cores in terms of the mass function of stars and substellar objects. Note that observers often use the word "core" to describe what we call here "dense regions."

5.1. Global Evolution

Figure 3 shows the evolution of the system for Run A ($N_{gen} = 0$). Gas particles are shown in blue, and sink particles in black. Following KB, we shall identify these sinks as protostellar cores, and from now on we shall use the term "sink" only when discussing the properties of the algorithm, rather than the physical interpretation of the results. Each panel is accompanied by three numbers, the time, the number of cores, and the percentage of mass accumulated in cores. The system evolves rapidly into a network of intersecting filaments. Around $t = 1$, cores start to form inside the dense knots located at the intersections

Fig. 3. Global evolution of the system, for Run A. Each box shows a snapshot of the system, with SPH gas particles represented by blue dots (for clarity, only 1/8 of the gas particles are plotted), and protostellar cores represented by large black dots. For each snapshot, the time in units of $(G)^{-1/2}$ is indicated in the top right corner, while the numbers in the top left corner indicate the number of cores and the fraction of the total gas that has been accumulated into cores, respectively.

Fig. 4. Final state of the system, for Run A (left), B (middle), and C (right). The symbols and labels have the same meaning as in Figure 3.

of the filaments. By $t = 1.2$, the densest knot already contains a large cluster of cores, and the filaments themselves start to fragment into cores. By $t = 1.6$, most of the filaments have disappeared, having turned into cores, and these cores are falling toward the main cluster. By $t = 2$, 90% of the gas has been turned into cores, and a dense cluster of cores has formed. During the later stages of the evolution, the remaining gas gets accreted onto the cores, and the cluster starts to evaporate: cores are ejected by close encounters, while the remainder of the cluster contracts and gets more tightly bound. All calculations terminate at $t = 2.5$, when 97% {99% of the gas has been turned into cores.

Figure 4 shows the final state of the system, at $t = 2.5$, for all three runs. The final location of the cluster is about the same for all three runs, but the total number of cores significantly increases as we allow more splitting generations. The final number of cores is 213, 964, and 2876 for Runs A, B, and C, respectively. Also, there is less gas remaining in the system for Runs B and C, compared to Run A.

Figure 5 shows a series of zooms at an early time slice ($t = 0.9030$) for Run C ($N_{\text{gen}} = 2$). The black, green, and blue dots represent the generation 0 (unsplit), generation 1 (split once), and generation 2 (split twice) particles. The masses of these different types of particles have ratios (64:8:1). As explained in §2.2 above, the first splitting occurs at density $\rho = 27.5$ and the second one at density $\rho = 1759$. Hence, the boundary between the black and green particles is an isosurface of density $\rho = 27.5$, and the boundary between green and blue particles is an isosurface of density $\rho = 1759$. Notice that these boundaries are quite sharply delimited, indicating that nothing peculiar is happening there. Indeed, the density varies smoothly across this entire region, and the transition between particles of widely different masses produces no observable feature in the density profile.

The bottom right panel of Figure 5 zooms in on the intersection of filaments to show a concentration of sinks (red circles), which have formed earlier and have moved toward each other as the density increases. In this region, a gas particle might be located inside the accretion radius of several sinks, in which case it will accrete onto the sink for which the total energy is the lowest (that is, the binding energy is highest), as explained in §2.4. The bottom left panel shows a further zoom-in on the filament to the lower left. In this particular case, the cylindrical collapse of a filament leads to the formation of a chain of sink particles separated by a distance equal to twice the accretion radius r_{acc} , reminiscent of observations of dense regions within filaments (Schneider & Elmegreen 1979). The circle shows the accretion radius for a particular sink. Gas particles that enter that accretion radius will be accreted by the sink (most particles appearing inside the circle in Fig. 5 are seen in projection).

Fig. 5. Early time slice ($t = 0.903$) of the evolution of the system, for Run C. Top left panel: the entire computational volume. For clarity, only $1/8$ of the particles are shown. Top right panel: zoom-in on a dense region at the intersection of two emerging filaments (with all particles shown). The colors black, green, and blue corresponds to particles of generation 0, 1, and 2, respectively. Sink particles are shown in red. Bottom right panel: zoom-in on the central, high-density region. Cavities around sink particles are visible. Bottom left panel: Zoom-in on a filament. The cavity around one sink particle is shown by a circle of radius $r_{\text{acc}} = 0.0005$. Particles appearing inside the cavity are either background or foreground particles.

5.2. Particle Splitting and Sink Particles

Figure 6 shows stacked histograms of the number of particles within each generation (left panels) and the total mass contained within each generation, and the division of mass between particles and sink particles (right panels). In the absence of particle splitting ($N_{\text{gen}} = 0$, Run A, top panels), the number of particles remains constant until sink particles are created, and then steadily decreases as sink formation and accretion onto sinks removes particles from the simulation. When particle splitting is included (Runs B and C, middle and bottom panels), the total number of particles N_{tot} initially increases as particles split, but this process competes with accretion onto sinks, and eventually N_{tot} decreases. In Table 2, we list, for each run, the initial number of particles N_{init} , the maximum number of particles N_{peak} reached during the simulation, and the effective number of particles N_e , defined as the number of particles a simulation without particle splitting would need to have the same resolution ($N_e = N_{\text{init}} f_{\text{split}}^{N_{\text{gen}}}$). Runs A, B, and C have effective resolutions of 64^3 , 128^3 , and 256^3 particles, respectively. Of particular interest is the ratio N_{peak}/N_e , given in the last

Fig. 6. Left panels: stacked histograms of the number of particles of various generations, versus time. The labels 0, 1, and 2 indicate the various generations of particles. The top curve on each panel shows the total number of particles, N_{tot} . Right panels: stacked histograms of the mass contained in each generation of particles, and in sinks, versus time. Top panels: Run A; middle panels: Run B; bottom panels: Run C.

column of Table 2. This ratio measures the "efficiency" of the particle splitting algorithm. As the number of splitting generations increases, the peak number of particles becomes significantly lower than the effective number of particles, resulting in a substantial saving of computational effort relative to a simulation without particle splitting. From Table 2, we can infer that every additional splitting generation makes the algorithm more "efficient" by a factor of order 4–5.

At this point, we need to discuss a possible alternative to particle splitting, called the "zoom-in" approach, which is often used in numerical simulations. This approach would consist of first running a low-resolution, $N = 64^3$ simulation, identifying in the final state of the simulation the particles located in "regions of interest," where higher resolution would be desirable, going back to the initial conditions, replacing these particles only by a set of smaller particles, and then redoing the simulation. This approach would fail in the present case for the following reason: As we shall see in the next section, about half of the gas particles in the simulation are eventually converted into sinks, while the other half get accreted onto existing

sinks. While high resolution might not be necessary for the particles that are accreted onto sinks, it is certainly necessary for the particles that are converted into sinks, in order to prevent artificial fragmentation. This means that, in the initial conditions, one half of the particles would have to be replaced by a cube of $4 \times 4 \times 4 = 64$ particles in order to provide sufficient resolution. The total number of particles would then be $N = 64^3 [1 + (4^3 - 1)/2] = 8,388,608$, or $256^3/2$. Hence, using a zoom-in approach would only reduce the number of particles by a factor of 2 compared with the brute force approach. The zoom-in approach is useful in situations where the "regions of interest" contain a small fraction of the total mass of the system. Here, these regions contain 50% of the mass, making this approach inefficient.

5.3. Regimes

Figure 7 shows the time-evolution of the number of cores and the total mass accumulated in cores. By comparing the time-evolution of these two quantities, we can identify four distinct phases during the evolution of the cloud, with each phase corresponding to a different dynamical regime.

The initial phase corresponds to the growth regime. The initial density fluctuations grow by gravitational instability, to form a network of dense, intersecting filaments. This phase of the evolution terminates when the first cores form. Since the density threshold ρ_c for sink formation is chosen arbitrarily, the end of this initial phase is also arbitrary. However, in the absence of sinks (and with infinite resolution), fragments would collapse and reach infinite densities at a finite time that would exceed the time of sink formation only slightly. Hence, choosing the time of formation of the first cores as corresponding to the end of the growth phase is not an unreasonable choice.

After the first cores form, the evolution of the cloud enters the second phase, which corresponds to the collapse regime. To understand this regime, and the following one, we must consider a fundamental property of Gaussian initial conditions: the filling factors of underdense (< 1) and overdense (> 1) regions are initially equal, both being $1/2$ of the total computational volume. Since the initial density is nearly uniform ($\rho \approx \rho_c$), about $1/2$ of the gas starts up in overdense regions, while the other $1/2$ starts up in underdense regions. In the collapse regime, the gas that started up in overdense regions collapses and is converted into cores. This regime is characterized by an increase in both the number of cores and the mass inside cores, at rates that are roughly proportional. This phase terminates when 50% of the gas, essentially the gas that started up in overdense regions, has been turned into cores.

The evolution of the cloud then enters the next phase, which corresponds to the accretion regime. The uncollapsed gas remaining in the cloud is the gas that started up in underdense regions. The main tendency of this gas is not to collapse onto itself and form new cores, but rather to accrete onto the existing cores. As a result, the mass in cores keeps increasing, while the number of cores levels off. During this phase, the

Table 2. Number of Particles.

Run	N_{init}	N_e	N_{peak}	N_{peak}/N_e
A	262,144	262,144	262,144	1.000
B	262,144	2,097,152	467,636	0.223
C	262,144	16,777,216	1,067,610	0.064

Fig. 7. Time-evolution of the mass accumulated in protostellar cores (dashed curve, left axis) and the number of cores (solid curve, right axis) versus time. The dotted lines separate the various phases of the evolution, with the corresponding regimes labelled on top.

mass in cores nearly doubles, while the number of sinks increases by less than 30%.

Finally, once most of the gas (90% or so) has been accumulated in cores, the evolution of the cloud enters the fourth and last phase, which corresponds to the N-body regime. The hydrodynamics becomes irrelevant, and the evolution of the system is governed by gravitational many-body dynamics.

5.4. Formation and Growth of Protostellar Cores; Low-Resolution Simulation

Figure 8 shows the natal masses of the protostellar cores as a function of their birth rank. We define the birth rank such that the n^{th} core formed in the simulation has a birth rank of n (KB use the term “index”). The top panel shows the results of Run A, without particle splitting, which can be directly compared to the results of KB. As KB noted, the mass tends to decrease with increasing birth rank, simply because cores formed later have less time to grow by accretion. However, the trend we observe is much less pronounced

Fig. 8. | Mass of protostellar cores versus birthrank. (a, top panel) Run A ($N_{\text{gen}} = 0$); (b, middle panel) Run B ($N_{\text{gen}} = 1$); (c, bottom panel) Run C ($N_{\text{gen}} = 2$). The various symbols (crosses, asterisks, and solid circles) identify particular cores that are discussed in the text.

than the one found by KB. The mass range is comparable, and the most massive cores all formed early (with the most massive one being the very first one that formed), but the distribution shown in Figure 8a reveals several low-mass cores that formed early, as well as several high-mass "peaks" with high birth ranks. Another surprising result, for Run A, is the normal mass of the most massive core, which is 35% of the total mass of the system. This core, the first one to form, clearly experienced runaway accretion. By contrast, the most massive core formed in any simulation of KB has a mass of order 6–8% of the total mass of the system. It is important to understand these various features. For the rest of §5.4, we will discuss the results from Run A; Runs B and C will be discussed in §5.5.

5.4.1. Early Ejections

The presence of cores in the bottom left corner of Figure 8a is easily explained. Some cores that form early can be ejected after experiencing close encounters with other cores. Once a core is ejected from the dense structure where it originally formed, it finds itself in a low-density region where there is little gas to accrete. The mass growth of that core then levels off at a constant value, a process discussed by KB. To illustrate this, we focus on 3 early-forming cores that end up with very low masses, cores # 8, # 10, and # 14 (crosses in Fig. 8a). Figure 9a shows the distribution of cores in the system at $t = 1:084$, just before core # 10 is ejected. The system at that time contains 19 cores, 10 of them forming a dense cluster embedded in a common gas filament (not shown). This cluster, indicated by the small square, is enlarged and displayed in Figure 9b. Figure 9c shows the trajectories of these 10 cores, from the locations where they formed (open circles) to their locations at $t = 1:154$ (solid circles). Several cores are ejected, including the cores # 8, # 10, and # 14.

Figure 9d shows the mass evolution of these 3 cores. After formation, their masses grow rapidly by accretion, until they are ejected. After being ejected, cores # 10 and # 14 no longer accrete gas, and remain at constant mass throughout the remainder of the simulation. Core # 10 is ejected at very large velocity (see the quasi-straight trajectory in Fig. 9c), and moves only through low-density regions thereafter. Core # 14 remains bound to the main cluster, but ends up orbiting the cluster at a "safe" distance, never coming close enough to accrete gas from the cluster's envelope. Core # 8 is ejected at low velocity, turns back, and falls into a dense clump at $t = 1:541$. Its mass then increases slightly by accretion. At $t = 1:904$, that clump, which still contains core # 8, merges with the main cluster. The mass of core # 8 increases again by accreting gas from the main cluster, before being ejected a second time, after which its mass remains constant.

5.4.2. Local Competitive Accretion

To understand the origin of the massive cores at high birth rank, we need to consider the nature of competitive accretion between cores. This process was described in detail by Bonnell et al. (1997, 2001). There are 4 basic arguments for why cores that form earlier should reach higher masses: (1) since they form earlier, they have more time to grow by accretion, (2) the cores that form early will deplete their surroundings by accretion, reducing the amount of gas available to cores that form later, (3) by being more massive, the cores that form early have a stronger gravitational potential than the ones forming late, making them more efficient in accreting the remainder of the surrounding gas, and (4) if several cores of different masses are present inside a gaseous clump, the most massive cores will tend to reside in the center of the clump where there is presumably more gas to accrete. While argument (1) is general, arguments (2), (3), and (4) are valid only if cores form out of the same clump, and are therefore competing for the same surrounding gas. If the final cluster forms by the merging of dense clumps, and if cores form in these clumps prior to the final merging, then there will be competitive accretion within each clump, but not across clumps. The very first core that forms in a particular clump can then grow by accretion and reach a high mass, no matter how late core formation in that clump started.

To illustrate that, we focus on 3 cores, cores # 141, # 151, and # 156, which are located in two late "peaks" (asterisks in Fig. 8a). The top panels in Figure 10 show the system at $t = 1:235$, immediately after the formation of core # 141. As we see, that core did not form inside the main cluster, but inside an emerging filament located away from the main cluster, and was the very first core to form there (core # 5 is a fast-moving core that was ejected early and is seen in projection). The bottom panels in Figure 10 show

Fig. 9. (a, top left panel) snapshot of the distribution of cores in the computational volume at $t = 1.084$. The system contains a total of 19 cores; (b, middle left panel) enlargement of the region indicated by a square in the previous panels, showing a dense cluster composed of 10 cores; (c, top right panel) the same cluster is shown at $t = 1.154$ (solid dots), along with the trajectories of the cores between $t = 0$ and $t = 1.154$ (curves). The cores # 8, # 10, and # 14, which are ejected, are indicated; (d, bottom panel) time evolution of the mass of cores # 8, # 10, and # 14.

the system at $t = 1.265$, immediately after the formation of core # 156. Again, cores # 151 and # 156 formed in a filament away from the main cluster, and were the first two cores to form there. Local competitive accretion enables these cores to grow and reach a high mass before they fall into the main cluster.

5.4.3. Violent Infall and Late Starburst

There is another peak in Figure 8a that we wish to consider. This peak contains cores with birth ranks 199{203 (solid circles in Fig. 8a), that formed very late. These 5 cores formed almost simultaneously, between $t = 1.595$ and $t = 1.609$, all inside a small region of diameter 0.006 located right in the middle of the cluster. Figure 11 shows a histogram of the formation time of cores. The formation of cores # 199{203 in Run A appears as a burst, which is indicated by an arrow in the top panel. We need to understand how this burst occurred and how these cores managed to reach a high mass in a such a crowded environment. Clearly,

Fig. 10. (a, top left panel) distribution of cores at $t = 1.235$, immediately after core # 141 formed; (b, top right panel) enlargement of the region indicated by a square in the previous panel, showing both gas particles (small dots) and cores (large dots). Cores # 5 and 141 are indicated by numbers; (c, bottom left panel) and (d, bottom right panel) similar to (a) and (b), but at time $t = 1.265$, immediately after core # 156 formed.

we cannot invoke local competitive accretion here, since these cores, unlike cores # 141, # 151, and # 156, formed in a region that already contained many other cores that were already significantly more massive.

Consider the state of the system at time $t = 1.5 - 1.6$ (see 8th and 9th panels in Fig. 3). At that stage, there is still a substantial amount of gas located far from the main cluster. Some of that gas, which is located in dense filaments, will form new cores, that will later fall into the main cluster. The remainder of the gas, which is located between the filaments, does not reach high enough densities to trigger the formation of cores. It will therefore remain in the form of gas until it falls into the main cluster. Because that gas comes from large distances, it gets accelerated over a long period of time, and therefore falls inside the main cluster at large velocities. This large velocity reduces the effectiveness of gravitational focusing, making it more difficult for that gas to accrete onto the cores already present in the cluster. Instead, that gas is rapidly decelerated by a strong shock and gets compressed to a very high density, which triggers the formation of several cores in a burst.

Fig. 11. Histogram of the number of protostellar cores versus their epoch of formation. (a, top panel) Run A ($N_{\text{gen}} = 0$); (b, middle panel) Run B ($N_{\text{gen}} = 1$); (c, bottom panel) Run C ($N_{\text{gen}} = 2$). The arrow in the top panel identifies the late starburst. The first three cores formed in Run A are also identified.

5.4.4. Runaway Accretion

To understand the very large mass of core # 1, we need to consider the formation history of the first few cores. Looking again at Figure 11a, we immediately notice something special about the first three cores. These cores formed at well-separated times, after which core formation proceeded very rapidly. Table 3 shows, for the first 5 cores, the quantity $m_i(t_j)$, defined as the mass of core i at the time of formation of core j (with $j > i$). All cores are created roughly with the same mass (diagonal in Table 3). However, core # 2 formed significantly later than core # 1, and during the time interval $t_2 - t_1$, core # 1 accreted more than 20 times its original mass (growing from 0.000435 to 0.009205), so that when core # 2 formed, core # 1 was already more massive by a factor of 23. The process then repeats itself: core # 3 formed significantly later than core # 2, and during the time interval $t_3 - t_2$, core # 1 and # 2 experienced significant growth. By $t = t_3$, these 3 cores have mass ratios 55:10:1. This process goes on, and by $t = t_4$, the first 4 cores have mass ratios 77:11:10:1 (core # 2 is ejected between t_3 and t_4 , and stops growing afterward). Finally, this process

terminates: core # 5 is created almost immediately after core # 4, providing little time for the latter to grow, so that at $t = t_5$, cores # 4 and # 5 have comparable masses. We are then in the "big peak" in Figure 11a, with many cores forming at comparable times.

5.5. Formation and Growth of Protostellar Cores; Higher-Resolution Simulations

We have focused so far on Run A, and investigated the origin of the various features found in Figure 8a. Figures 8b and 8c show the results for Runs B and C, respectively. The results are qualitatively similar to Run A. There is a definite tendency of the mass to decrease with increasing birth rank. The distributions are very wide, however, and show several peaks at high birth rank, which we again attribute to competitive accretion.

5.5.1. Early Ejections

There is a noticeable difference in the higher-resolution runs: the absence of very-low mass cores at small birth ranks. Early ejections seem far less common in these simulations. This can be explained using the following argument. Consider an envelope of gas of mass M and radius R , containing several cores of mass m , forming a small, bound cluster of radius r , inside which the mean core spacing is λ . The gravitational force f between cores is proportional to m^2/λ^2 , and therefore the acceleration a of the cores varies with mass as

$$a = \frac{f}{m} \propto \frac{m^2/\lambda^2}{m} \propto \frac{m}{\lambda^2} : \quad (24)$$

For a fixed cluster radius r , the core spacing λ depends on the number of cores, and for a fixed cluster mass, that number of cores depends on the resolution, such that $\lambda \propto m^{-1/3}$ (if the mass per core is smaller, the cluster contains more cores, thus those cores are closer to one another). Hence $a \propto m^{1/3}$. If a core is ejected from the cluster, its terminal velocity should be of order $v \propto (2ar)^{1/2} \propto m^{1/6}$. But the escape velocity from the whole system is of order $v_{\text{esc}} \propto (GM/R)^{1/2}$, independent of m . Therefore, lowering m makes it more difficult for cores ejected from the cluster to escape the common envelope of gas.

Table 3. Mass of the First Cores (10^3).

Mass	$t_1 = 0.9010$	$t_2 = 0.9522$	$t_3 = 1.0055$	$t_4 = 1.0356$	$t_5 = 1.0361$
m_1	0.435	9.205	21.942	31.693	31.925
m_2		0.405	3.922	4.494	4.494
m_3			0.401	4.166	4.242
m_4				0.412	0.435
m_5					0.381

5.5.2. Local Competitive Accretion and Late Starburst

Figures 8b and 8c show several peaks, corresponding to high-mass cores with high birth ranks. We examined several cases, indicated by asterisks. In all cases, we found that the high masses resulted from local competitive accretion. All these cores formed in regions located away from the main cluster, often in emerging filaments. In several cases, these filaments contained a string of cores (as seen, for instance, in Fig. 5), and the core that reached a high mass was the one located at the very end of the string. This is an example of local competitive accretion, and perhaps the core at the end is able to accrete from a larger solid angle.

We did not find a late starburst (or coreburst) in the high-resolution simulations. The gas located in very low regions does fall into the cluster in the form of gas, but tends to be accreted onto the cores rather than forming new cores. Accretion is much more efficient in the higher-resolution simulations simply because of the sheer number of cores in the cluster at late time. That number is very small for Run A because (1) core # 1 contains more than half the total mass of the cluster, and (2) as we shall see in §5.6, the cluster suffers a great deal of evaporation at late time in Run A. Hence, the cross section for accretion onto cluster cores is greatly reduced in the low-resolution simulation compared with the high-resolution ones, which explains why the late starburst phenomenon is seen only at low resolution.

5.5.3. Runaway Accretion

We did not observe the kind of runaway accretion experienced by the first core in Run A. While that core reaches a total mass of 0.358 (35.8% of the total mass in the computational volume), the total masses of the first cores formed in Runs B and C are 0.00295 and 0.000803, respectively. Actually, the core which ends up with the largest mass in Run C is not core # 1, but rather core # 707, with a total mass of 0.00263. In Run A, runaway accretion occurred because the first core formed significantly earlier than the others. With higher resolution, several lower-mass cores form almost simultaneously inside the first region that reaches the threshold density, and competitive accretion among these cores prevents runaway accretion.

Comparing all these results with the ones presented in §5.4, we conclude that local competitive accretion is a fundamental process that occurs at all resolutions, except in situations where a small number of cores results in the formation of a single cluster (as in the simulations of KB). In such a case, competitive accretion does occur, but it is not local. Other phenomena, like early ejection, late starburst, and runaway accretion, appear to be peculiarities of low-resolution runs, and become less common as the resolution increases.

5.6. The Protostellar Cluster

All three simulations end up forming a dense cluster of protostellar cores. In this section, we study the assembly history and structure of that cluster.

5.6.1. Mass and Cluster Members

To identify the cores that belong to the cluster, we first use visual inspection to make an initial estimate $(r_{cl})_{init}$ of the center of the cluster. Then, using an iterative method, we find a self-consistent solution for

Fig. 12. (a, top panel) evolution of the number of cores inside the main cluster; (b, bottom panel) evolution of the mass in cores inside the main cluster. On both panels, the three curves correspond to Run A ($N_{\text{gen}} = 0$, solid curve), Run B ($N_{\text{gen}} = 1$, dotted curve), and Run C ($N_{\text{gen}} = 2$, dashed curve). On the top panel, the number of cores for Runs A and B have been multiplied by factors of 25 and 2.75, respectively, to allow a better comparison. The thick vertical lines indicate the transitions between the collapse, accretion, and N-body regimes, as indicated.

the center of mass r_{cl} and radius r_{200} of the cluster, such that (1) the center of mass of the cores located inside a sphere of radius r_{200} centered on r_{cl} is indeed r_{cl} , and (2) the mean density ρ_{200} inside that sphere is 200 times the mean density in the system. Notice that these densities are computed using the cores only, without the gas, as in KB.

Figure 12a shows the time-evolution of the number of cores in the cluster, for all three runs. We have rescaled the number of cores for Runs A and B by factors of 25 and 2.75, respectively, for comparison with Run C. The number of cores for Run A (solid curve) varies tremendously, in a somewhat chaotic way. These large fluctuations can be attributed to small statistics, Run A having the smallest total number of cores. However, this is not the only explanation. Our method for determining cluster membership assumes spherical symmetry, but in Run A, the cluster tends to be triaxial during most of the calculation, and also the sphere of radius r_{200} which contains the cluster members tends to follow the motion of core # 1, since that core contains most of the mass of the cluster. So as core # 1 experiences brownian motion around the

center of the cluster, cores located near the surface of the sphere keep "falling" in and out of the cluster. This does not occur with the higher-resolution runs, because the cluster tends to be quite spherical, and no single core dominates its mass.

During the collapse regime ($t < 1.34$), cores are forming inside the cluster, increasing the number of cluster members. There are few ejections during this phase, and the net effect is a near-monotonic increase in the number of cores. Once the system enters the accretion regime, few new cores are forming, and the competing processes are ejections from the cluster and accretion of cores that formed in secondary clumps outside the main cluster. Indeed, the main cluster experiences a major merger with another, comparable cluster, at $t = 1.29$, near the end of the collapse phase, resulting in a sudden increase in the number of cores. For Runs B and C, the number of cores tends to increase during the accretion regime, indicating that accretion of cores formed in subclumps dominates over ejections. For Run A, however, the ejections tend to dominate. Once the system enters the N-body regime ($t > 2.02$), the number of cores steadily decreases for Runs A and B. All the cores formed outside the main cluster have been accreted along with the remaining gas, and ejections become the dominant process. However, the number of cores in Run C remains nearly constant, indicating that very few ejections are taking place.

Figure 12b shows the evolution of the mass of the cluster. The results are nearly identical for all three runs up to $t = 1.29$, when the major merger takes place. From that point, Run A differs significantly from the other two runs, as the mass of the cluster grows much more slowly. Interestingly, in the N-body regime, the mass of the cluster, for Run A, remains nearly constant even though the number of cores drops significantly. This indicates that only low-mass cores are ejected at late time.

The most striking result shown in Figure 12b is the similarity between the results of Runs B and C. The curves are essentially indistinguishable up to the beginning of the accretion phase, and then remain very similar up to the end of the simulation, having in particular the same local maxima at $t = 1.33, 1.58$, and 2.05 , and the same local minima at $t = 1.37$ and 1.61 . Notice also the sudden increase in mass at $t = 1.54$, corresponding to a merger with a smaller subcluster of cores. This merger does not occur in the low-resolution simulation.

5.6.2. The Density Profile

We computed the density profile of the cluster by adding up the mass of the cores inside radial bins. Figure 13 shows the evolution of the profile, for all three runs. For Run A, the profile is very steep at the center, simply because core # 1, which undergoes runaway accretion, totally dominates the mass of the cluster. For Runs B and C, the cluster profile starts up roughly as a power law, but soon acquires a core/halo structure, as in the simulations of KB. In these two runs, the central density drops and the profile flattens at late time ($t > 2$), corresponding to the epoch where the total mass of the cluster stops growing (see Fig. 12). At these late times, the central part of the cluster flattens, probably as a result of gravitational heating by tight binary cores.

Figure 14 shows a comparison among the three runs of the cluster profile at some particular times ($t = 1.13, 1.5$, and 2). The density profiles found in Runs B and C are very similar, at all epochs. This is quite striking, considering that the number of cores in the cluster roughly quadruples between $t = 1.13$ and $t = 2$, while the mass in the cluster increases by a factor of 9. The profile for Run A is totally different. Most of the mass of the cluster is contained in core # 1, located in the center of the cluster.

Fig. 13. Density profile of the main cluster, for Runs A (top panel), B (middle panel), and C (bottom panel). The various curves correspond to different times, from bottom to top: $t = 1.00$ (bottom curves), 1.13, 1.50, 2.00, and 2.50. There is no curve plotted for $t = 1.00$ in the top panel because the cluster contained only two cores at that time in Run A.

5.7. Initial Mass Function of Protostellar Cores

Figure 15 shows the initial mass distribution of protostellar cores at $t = 2.5$, when nearly all the gas has been accreted. For Run A, the existence of a core containing 35% of the total mass of the system results in a skewed distribution. Interestingly, the simulations of Tilley & Pudritz (2004) show similar features (Fig. 17 in their paper), suggesting that runaway accretion is happening in their simulations as well. For Runs B and C, the distributions are roughly log-normal, with some skewness toward high masses, as the dashed curves show. KB reported that the mass distribution peaks at the initial Jeans mass of the system. Our results are consistent with that claim, but only for Run A. As the number of splitting generations, or equivalently the mass resolution of the algorithm, increases, the distribution shifts to lower masses while keeping the same width in $\log M$. Clearly, it is the resolution, and not the initial Jeans mass, that determines the location of the peak. As the resolution increases, the algorithm can form cores with smaller masses, until the resolution is so high that the Jeans mass $(M_J)_c$ at the threshold density ρ_c is resolved. Hence, increasing the

Fig. 14. Density profile of the main cluster at times $t = 1.13, 1.50$, and 2.00 , as indicated. The solid, dotted, and dashed curves correspond to Runs A, B, and C, respectively. The numbers in the bottom left corner of each panel indicate the number of cores in the cluster at these times (top number: Run C; middle number: Run B; bottom number: Run A).

resolution moves the low-mass end of the distribution to lower masses. This leads to the formation of a larger number of cores, which then have to compete for accretion. As a result, the high-mass end of the distribution also moves to lower masses. Note that the shift to lower masses results only from increasing N_{gen} because ϵ_c is the same in all three runs.

These log-normal distributions (for Runs B and C) are consistent with the numerical results of KB. However, they are inconsistent with observations that show a peak at small masses and a power-law like behavior at the high-mass end. There are several possible explanations for this. Once sinks form, they can no longer fragment. In the real world, these objects might fragment, increasing the number of low-mass objects relative to high-mass ones (notice that sink merging, which we also ignore, would have the opposite effect). We did not take turbulence into account in these simulations. Turbulence could affect the dynamical evolution of the system differently at different scales, affecting the final shape of the mass distribution. Probably even more importantly, feedback effects, if included, could slow down the growth of

Fig. 15. Mass distribution of protostellar cores. (a, top panel) Run A ($N_{\text{gen}} = 0$); (b, middle panel) Run B ($N_{\text{gen}} = 1$); (c, bottom panel) Run C ($N_{\text{gen}} = 2$). On each panel, the left and right dotted lines indicate the Jeans mass at densities ρ_c and ρ_* , respectively. The dashed curves show the results of a least-square fit to a log-normal distribution.

massive cores by accretion. Finally, we could consider changing the slope of the power spectrum of initial density fluctuation, though KB did this (Klessen & Burkert 2001), and found that the distributions of core masses remained log-normal.

6. CONVERGENCE

The three simulations we have performed all start with 64^3 particles, and use identical initial conditions. However, particle splitting increases the effective resolution of the simulations, which is 128^3 for Run B and 256^3 for Run C. Since the initial conditions are identical but the effective resolution varies, this set of simulations constitutes a convergence study, which can be used to estimate the minimum resolution necessary to obtain reliable results.

It is clear, however, that some results simply will not converge. By requiring that sink particles are created with enough gas particles to insure that they are resolved (that is, Scenario II, by opposition to Scenario I), the initial mass of sinks depends on resolution, and as a result the IMF of cores shown in Figure 15 shifts to lower masses as the resolution increases. However, the results of Run C have converged, since that simulation does resolve the Jeans mass. If we added a Run D with $N_{\text{gen}} = 3$ to our set of simulations, the results of Runs C and D would be identical, because a third level of splitting would never occur: before the density gets large enough to make particles split a third time, these particles would turn into sinks (see Fig. 2). This convergence is numerical in the sense that numerical parameters like ϵ_c and N_{gen} determine the solution that the simulation converges to. A solution that would converge physically does not exist, and therefore cannot be achieved, in a system with an isothermal equation of state, because no physical process limits the minimum mass of cores. In the real universe, the assumption of isothermality breaks down at high densities when the gas becomes optically thick, and that in turn leads to a physical minimum mass for cores.

Looking at the macroscopic properties of the final cluster of cores, it is clear that the results of Runs A and B are significantly different, while the results of Runs B and C are very similar, indicating that convergence has been achieved. In particular, the mass history of the cluster (bottom panel of Fig. 12) and the density profile at various times (Fig. 14) are strikingly similar for Runs B and C. In Run A, the first core formed underwent runaway accretion, which affected the further evolution of the cluster. No such runaway accretion occurred in Runs B and C. We believe that the likelihood of such occurrence is reduced as the resolution increases, because as more cores are formed, the time interval between the formation of a core and the next one is reduced, thus increasing the competition for accretion.

Finally, there are other results, arguably less interesting, that show convergence. In particular, the formation time histograms shown in Figure 11 are quite similar for Runs B and C, and different for Run A, with the bulk of the cores forming at later time.

7. ILLUSTRATIVE EXAMPLES

To compare the results to observations, it is convenient to use the relations in x4.3 to convert the densities, masses, etc. to physical units. Because the simulations contain 500 Jeans masses initially, the total mass and other properties are uniquely fixed by a choice of temperature and density. We set the temperature at 10 K for all these examples because this temperature is characteristic of both dust and gas temperatures in well shielded regions before stars form (Leung 1975; Evans et al. 2001; Young et al. 2004). We will consider below constraints imposed by the assumption of isothermality. Observers commonly use total particle density $[n = n(\text{H}_2) + n(\text{He})]$, where $\rho = n m_{\text{H}} n$, with m_{H} the atomic mass unit. For a fully molecular cloud with 25% helium by mass, $n_{\text{H}} = 2.29$. We will use n for the initial density.

With equation (19) for the Jeans mass, we have in physical units: $M_{J,\text{init}} = 6.33 T^{1.5} n^{-0.5} M_{\odot} = 200 n^{-0.5} M_{\odot}$ for $T = 10 \text{ K}$. It follows that $M_{\text{tot}} = 1.0 \cdot 10^6 n^{-0.5} M_{\odot}$, and the size of the region, $L_{\text{box}} = (M_{\text{tot}} =)^{1/3} = 121 n^{-0.5} \text{ pc}$. The dynamical time, $t_{\text{dyn}} = (G \rho)^{-1/2} = 6.3 \cdot 10^7 n^{-0.5} \text{ yr}$. Values for these quantities are given in Table 4 for different values of n .

The assumption that the gas remains isothermal depends on its ability to cool. In dense regions, the gas cools by collisions with dust grains, which radiate in a continuum (Goldreich & Kwan 1974; Doty & Neufeld 1997; Young et al. 2004). To remain isothermal, the optical depth in the continuum near the peak emission wavelength should be less than unity, measured from the center of the region to the edge. The initial optical

depth is computed from $\tau = L_{\text{box}} \kappa = 2$, where κ is the opacity of dust per gram of gas. Emission from dust at 10 K peaks at a wavelength around 350 μm . Calculations of dust opacities for dust that has coagulated and acquired ice mantles, as may be expected in dense regions, have been done by Ossenkopf & Henning (1994). Observations are generally well matched by the opacities from column 5 in their table, known as OH5 opacities. The value for 350 μm , assuming a gas to dust ratio of 100, is $0.1 \text{ cm}^2 \text{ g}^{-1}$ of gas. The values of τ in Table 4 are computed from these assumptions.

Because we form sinks at a density $f_{\text{sink}} = 4 \times 10^4$ times the initial density (using the notation of x3.1), we must check that the region around the sink is optically thin just before sink formation. A convenient measure for this is the optical depth calculated for the radius of the SPH kernel at $\rho_c = f_{\text{sink}}$. The radius of the kernel is about 3 times the local particle spacing r . The particle spacing is constrained by $r = 0.5 L_{\text{box}} f_{\text{sink}}^{1/3} n_{\text{part}}^{-1/2} N_{\text{gen}}^{-1/2}$, where n_{part} is the initial number of particles along the edge of the computational volume (64 for these simulations). Thus, we have for the center to edge optical depth of a kernel, $\tau_{\text{kem}} = F$, where $F = 6 f_{\text{sink}}^{2/3} n_{\text{part}}^{1/2} N_{\text{gen}}^{-1/2}$. For $N_{\text{gen}} = 0, 1, 2$, $F = 109.6, 54.8, 27.4$. Particle splitting helps to keep the optical depth in a kernel from rising too far above the initial value, since increasing N_{gen} lowers F . Note that $\tau_{\text{kem}} \propto n^{-0.5}$ because of the scalings compelled by assuming that we have 500 Jeans masses. With the criterion that $\tau_{\text{kem}} < 1$, these calculations would be valid up to $n = 10^6 \text{ cm}^{-3}$, so we do not show any entries in Table 4 with n above that value. With $f_{\text{sink}} = 4 \times 10^4$, the maximum density would be about $4 \times 10^9 \text{ cm}^{-3}$. Alternatively, we could use the accretion radius (r_{acc} , see x2.4) instead of the kernel radius. These two radii turn out to be very similar, so the results are not significantly affected.

The 4 cases listed in Table 4 are simply scaled to different values of the initial density. The first is roughly similar to the example given by Klessen & Burkert (2000), which they compare to the Taurus cloud. Our case 1 has about twice the mass of that of KB because we have roughly twice as many Jeans masses. Our definition of Jeans mass is slightly different, and other differences combine to make our value for L_{box} about twice their value. The cases with higher initial densities approximate the conditions in cluster forming regions. Case 3 is similar to the conditions in the L1688 (Ophiuchus) cluster, which has 500–1000 $M_{\odot}$ in a region extending about 1 pc (Johnstone et al. 2000). Case 4 approximates conditions in the massive, dense regions studied by Shirley et al. (2003a); the median radius of gas traced by CS emission in their study is 0.37 pc, and the mean virial mass is about 1200 $M_{\odot}$. Mass estimates based on the 350 μm emission (Mueller et al. 2002) for a subsample of those sources yield mean values around 300 $M_{\odot}$.

Putting the mass functions shown in Figure 15 into physical units is probably premature because we have not yet included many effects, such as feedback from early star formation. If we proceed with these caveats in mind, we find that the mass function, in the simulation with $N_{\text{gen}} = 2$, and for Case 3, peaks around $0.3 M_{\odot}$, with a maximum mass around $2.0 M_{\odot}$ and a minimum mass of $0.03 M_{\odot}$, well into the

Table 4. Physical Quantities

Case	n (cm^{-3})	ρ (g cm^{-3})	M_{tot} ($M_{\odot}$)	L_{box} (pc)	t_{dyn} (yr)	τ (neper)	τ_{kem} (neper)
1	10^2	3.8×10^{-22}	1.0×10^4	12.1	6.28×10^6	6.9×10^{-4}	1.9×10^{-2}
2	10^3	3.8×10^{-21}	3.2×10^3	3.8	1.99×10^6	2.2×10^{-3}	6.0×10^{-2}
3	10^4	3.8×10^{-20}	1.0×10^3	1.21	6.28×10^5	6.9×10^{-3}	1.9×10^{-1}
4	10^5	3.8×10^{-19}	3.2×10^2	0.38	1.99×10^5	2.2×10^{-2}	6.0×10^{-1}

region of brown dwarfs. Case 4 produces even lower mass objects, with a peak in the distribution around $0.1 M_{\odot}$. This is not surprising since there is no limit to how small the Jeans mass may get with an isothermal equation of state. Clearly the other effects, which are the subject of future work, will need to be included before these distributions can be compared to the observed mass functions.

8. DISCUSSION

We have performed three simulations of fragmenting molecular clouds, using identical initial conditions, but different levels of particle splitting. Each additional level corresponds to an increase by a factor of 2 in length resolution and 8 in mass resolution. We have discovered several interesting phenomena, which we described in §5 above. Some of the results, such as the runaway accretion and the late starburst, were found only in the lowest-resolution simulation, and thus are clearly resolution-dependent. Such phenomena are peculiarities that happen sometimes when the number of cores is relatively small. We found three results that are not resolution-dependent: (1) the existence of four distinct regimes in the evolution of the cloud, (2) the phenomenon of local competitive accretion, and (3) the tight relationship between the mass range of the IMF and the resolution limit of the algorithm, until the calculation is fully resolved.

In these initial simulations, we have neglected several physical processes, such as turbulence, non-isothermality, and feedback, which will be addressed in future work. We believe that the three main results stated above are robust, and will remain valid once we include additional physical processes (though this remains to be proven). First, the existence of the four distinct regimes should not be affected by additional physics. The gas will always end up into cores given enough time, so there will always be a N -body regime at the late stages. The fact that half the gas turns into cores during the growth regime, while the other half is accreted during the accretion regime, is most likely a consequence of the Gaussianity of the initial conditions.

Local competitive accretion occurs because the timescale for the fragmentation of subclumps into cores is shorter than the timescale for these clumps to merge and form the final cluster. This could possibly be affected by turbulence or feedback, since these processes could delay core formation inside subclumps. In particular, the feedback from the first core forming in a given subclump could possibly prevent the formation of other cores in the same subclump, so that the final cluster would form by the merger of several subclumps, each one containing only one core. It remains to be seen if the effect of feedback could be that drastic.

We need a particular mass or length scale in the problem to determine the mass range of the IMF. In our simulations, the gas is isothermal, and there are no physical scale in the system. It is then a numerical scale, the minimum Jeans mass resolved by the algorithm, that determines the lower edge of the IMF. In simulations with a barotropic equation of state, the scale corresponds to the Jeans mass at the density where the gas becomes adiabatic. Turbulence and feedback could introduce a physical scale as well. But in all cases, there is no apparent reason for having a relationship between the mean initial Jeans mass and the lower edge of the IMF. Whatever the initial Jeans mass is, we expect the cloud to fragment down to the lowest mass scale allowed by either the physical processes or the numerical resolution.

9. SUMMARY AND CONCLUSION

This paper presented simulations of the fragmentation of a molecular cloud in which artificial fragmentation is prevented by using particle splitting, a technique that had not yet been applied to this kind of problem. With this technique, we can follow the evolution of the entire cloud, from the initial conditions to the formation of a star cluster, while fully resolving the Jeans mass at all densities.

The main objective of this paper was to demonstrate the feasibility of simulating the formation of a star cluster by cloud fragmentation, while properly resolving the Jeans mass throughout the entire simulation. We have successfully shown that, with the use of particle splitting, this can be achieved at a small fraction of the computational cost of a standard high-resolution or a "zoom-in" simulation. In particular, our largest simulation (Run C), which fully resolves the Jeans mass, has an effective resolution of 256^3 , or 17 million particles, while the actual number of particles in that simulation varies but never exceeds 1.1 million. The gain in performance is huge, and would only increase with additional splitting generations.

We have identified four distinct phases in the evolution of the cloud, corresponding to four different regimes. Initially, the cloud is in the growth regime. Overdense regions become denser and eventually form a network of filaments. Then, in the collapse regime, the gas in dense regions is converted into protostellar cores. In the accretion regime, the remaining gas, which started up in underdense regions, is mainly accreted by the existing cores. Finally, in the N-body regime, most of the gas has disappeared, and the evolution of the cluster is governed by N-body dynamics. These various regimes were certainly present in previous simulations, such as the ones of KB, but were not explicitly identified. The existence of a collapse and an accretion phase, and the fact that roughly 50% of the gas is removed during the collapse phase and 50% during the accretion phase, is most likely a mere consequence of the Gaussianity of the initial conditions, though this remains to be tested.

In the lowest-resolution simulation, we have noticed several interesting phenomena, such as early ejection, local competitive accretion, late starburst, and runaway accretion. Early ejections (also noticed by KB and Bate, Bonnell, & Bromm 2002b) occur during few-body encounters, and explain how cores that form early stop accreting and end up having a low mass. Local competitive accretion is a new phenomenon that we have identified. It occurs when several clumps of gas fragment to form sub-clusters of cores that later merge to form the final cluster. The first core formed in each clump does not compete for accretion until other cores form in the same clump, and can therefore reach high masses even if it formed late in the overall simulation. This explains most of the high-mass peaks at high birth ranks seen in Figure 8. Late starburst is caused by gas that was never dense enough to form cores until it falls into the main cluster at late times and gets suddenly shocked to very high densities. Runaway accretion occurs when the first core formed in the simulation formed significantly earlier than the next cores, and thus gets an early start in accreting gas. The mass difference then increases as a result of competitive accretion, and that core ends up containing a large fraction (up to one third) of the mass of the entire system. While all these phenomena were observed in the lowest-resolution simulation, only local competitive accretion was observed in the higher-resolution simulations. This suggests that local competitive accretion is a fundamental process that greatly affects the evolution of the system, while the other phenomena are less fundamental, and might not have occurred at all (or to a very different extent) if we had used different initial conditions. We believe that it is the small number of cores formed in the lowest-resolution simulation, and not its inability to resolve the Jeans mass, that is responsible for the occurrence of these phenomena.

The final distribution of the core masses are roughly log-normal (in agreement with the isothermal simulations of KB), except for the lowest-resolution simulation, where the runaway accretion of core # 1

results in a very skewed distribution. The location of the distribution shifts to lower masses as the resolution increases, until the resolution is sufficient to resolve the Jeans mass. This is a consequence of our decision to follow "Scenario II" for the simulations with $N_{\text{gen}} = 1$ and 2, requiring that dense clumps are converted into cores only if they contain at least n_{min} particles. Had we followed Scenario I, all simulations would have produced (presumably) distributions with the same mean. We found that the mean of the distribution is determined entirely by the resolution, and not by the mean Jeans mass at the initial time, in contradiction with the claim of KB.

This work benefited from stimulating discussions with A. Burkert, R. Fischer, R. Klees, C. Matzner, J. Scalo, A. Urban, and A. Whitworth. We thank the referee for very helpful comments. All calculations were performed at the Texas Advanced Computing Center. We are pleased to acknowledge the support of NASA Grants NAG 5-10825, NAG 5-10826, and NAG 5-13271. H.M. thanks the Canada Research Chair program and NSERC for support.

A . INITIAL CONDITIONS

The technique used for generating initial conditions is a generalization of the Zel'dovich approximation commonly used for cosmological simulations. The same technique was used by KB, but their description lacks details. In this appendix, we provide a more detailed description. Notice that most of this derivation can be found in §2 of Coles & Lucchin (1995).

To set up initial conditions, we lay down N equal-mass particles on a uniform cubic lattice inside the computational volume, and displace these particles to represent the density perturbation as a Gaussian random field with a particular power spectrum. We then adjust the particle velocities by requiring that the perturbation is growing with time. First, we start with equations (1), (2), and (4). We eliminate δ using $\delta = (1 + \delta)^{-1}$, where δ is the density contrast. Then, assuming that the perturbation is initially small, we neglect the pressure gradient, and only keep terms that are linear in δ , v , and $\dot{\delta}$. Equations (1), (2), and (4) reduce to

$$\frac{\partial}{\partial t} + r \cdot \nabla v = 0; \quad (\text{A } 1)$$

$$\frac{\partial v}{\partial t} = -r \cdot \nabla \delta; \quad (\text{A } 2)$$

$$r^2 = 4G\delta : \quad (\text{A } 3)$$

To solve these equations, we first take the divergence of equation (A 2). This introduces a term in $r \cdot \nabla v$, which we eliminate using equation (A 1), and a term in r^2 , which we eliminate using equation (A 3). We get

$$\frac{\partial^2}{\partial t^2} = 4G\delta = \dot{\delta}^2; \quad (\text{A } 4)$$

where $\dot{\delta}^2 = (4G\delta)^{1/2}$. The general solution is

$$(r;t) = A(r)e^{\dot{\delta}t} + B(r)e^{-\dot{\delta}t}; \quad (\text{A } 5)$$

We assume that at the initial time t_i , the perturbation is in a pure growing mode, and therefore $B = 0$. Equation (A 5) reduces to

$$(r;t_i) = A(r)e^{\dot{\delta}t_i}; \quad (\text{A } 6)$$

To solve for the velocity, we decompose the density contrast and velocity into sums of plane waves,

$$\delta(\mathbf{r}; t_1) = e^{i t_1} \sum_{\mathbf{k}} A_{\mathbf{k}} e^{-2 i \mathbf{k} \cdot \mathbf{r}}, \quad (\text{A } 7)$$

$$\mathbf{v}(\mathbf{r}; t_1) = \sum_{\mathbf{k}} \mathbf{v}_{\mathbf{k}} e^{-2 i \mathbf{k} \cdot \mathbf{r}}, \quad (\text{A } 8)$$

where the sums are over all plane waves that satisfy the periodic boundary conditions and whose frequency does not exceed the Nyquist frequency,

$$\mathbf{k} = (n_1; n_2; n_3) = L_{\text{box}}; \quad n_1, n_2, n_3 = 0; 1; 2; \dots; n_{\text{Nyq}}; \quad (\text{A } 9)$$

where $n_{\text{Nyq}} = N^{1/3} = 2$. We substitute equations (A 7) and (A 8) into equation (A 1), which becomes

$$i e^{i t_1} \sum_{\mathbf{k}} A_{\mathbf{k}} e^{-2 i \mathbf{k} \cdot \mathbf{r}} = 2 i \sum_{\mathbf{k}} \mathbf{k} \cdot \mathbf{v}_{\mathbf{k}} e^{-2 i \mathbf{k} \cdot \mathbf{r}}. \quad (\text{A } 10)$$

Since the plane waves are orthogonal functions, equation (A 10) implies

$$i e^{i t_1} A_{\mathbf{k}} = 2 i \mathbf{k} \cdot \mathbf{v}_{\mathbf{k}}. \quad (\text{A } 11)$$

To solve for $\mathbf{v}_{\mathbf{k}}$, we make the assumption that the velocity field is vorticity-free. This implies that $\mathbf{k} \cdot \mathbf{v}_{\mathbf{k}} = 0$, and therefore $\mathbf{v}_{\mathbf{k}} = \mathbf{j} \times \mathbf{k} v_k$ and $\mathbf{k} \cdot \mathbf{v}_{\mathbf{k}} = \mathbf{j} \times \mathbf{k} \cdot \mathbf{k} v_k$, where $\mathbf{k} = k \mathbf{j}$. Equation (A 11) then gives

$$\mathbf{v}_{\mathbf{k}} = \frac{i A_{\mathbf{k}} \mathbf{k}}{2 k^2} e^{i t_1}; \quad (\text{A } 12)$$

and equation (A 8) becomes

$$\mathbf{v}(\mathbf{r}; t_1) = \frac{i e^{i t_1}}{2} \sum_{\mathbf{k}} \frac{A_{\mathbf{k}} \mathbf{k}}{k^2} e^{-2 i \mathbf{k} \cdot \mathbf{r}}. \quad (\text{A } 13)$$

To compute the particle displacements $(\mathbf{r})_i$, we integrate the velocity between times t_1 and t_2 ,

$$(\mathbf{r})_i = \frac{i e^{i t_1}}{2} \sum_{\mathbf{k}} \frac{A_{\mathbf{k}} \mathbf{k}}{k^2} e^{-2 i \mathbf{k} \cdot \mathbf{r}_i} = \frac{\mathbf{v}(\mathbf{r}; t_1)}{i}; \quad (\text{A } 14)$$

For a given set of complex amplitudes $A_{\mathbf{k}}$, the displacements and velocities can be computed using equation (A 13) and (A 14). The amplitudes can be written as

$$A_{\mathbf{k}} = \mathcal{A}_{\mathbf{k}} e^{i \phi_{\mathbf{k}}}; \quad (\text{A } 15)$$

where $\phi_{\mathbf{k}}$ is a random phase with uniform probability between 0 and 2π , and $\mathcal{A}_{\mathbf{k}}$ is related to the power spectrum by

$$P(k) = \mathcal{A}_{\mathbf{k}}^2; \quad (\text{A } 16)$$

Notice that the phases must satisfy the condition $\phi_{-\mathbf{k}} = \phi_{\mathbf{k}}$ for $\mathbf{r}$ and $\mathbf{v}$ to be real. We assume a power spectrum of the form

$$P(k) = c k^{-n}; \quad (\text{A } 17)$$

where c is a constant. The displacements and velocity depends upon c and t_i only through the quantity $c^{1/2} e^{t_i}$. This quantity is arbitrary, but must be chosen sufficiently small that $(r; t_i) \ll 1$, otherwise this linear treatment is not valid. As KB point out, it must not be chosen too small either, otherwise the early evolution of the system would proceed very slowly, resulting in an excessive amount of CPU time just to get to the nonlinear regime. We generated initial conditions by imposing that the largest particle initial displacements $(r)_i$ are equal to 10% of the mean particle spacing. This limits the initial values of $(r; t_i)$ to be in the range $0.3 \leq (r; t_i) \leq 0.3$.
