Understanding the Nuclear G as D ispersion in Early-Type G alaxies in the C ontext of B lack H ole D em ographics¹

GipA.VerdoesKlein,^{2;3} Roeland P.van derMarel,⁴ Jacob Noel-Storr^{4,5}

ABSTRACT

The majority of nearby early-type galaxies contains detectable amounts of emissionline gas at their centers. The nuclear gas kinem atics form a valuable diagnostic of the central black hole (BH) mass. Here we analyze and model HST/STIS observations of a sam ple of 27 galaxies; 16 Fanaro & Riley Type I radio galaxies and 11 (m ore) norm al early-type galaxies. We focus here on what can be learned from the nuclear velocity dispersion (line width) of the gas as a complement to the many studies dealing with gas rotation velocities. We nd that the dispersion in a ST IS aperture of 0.1^{10} 0.2^{0} generally exceeds the large-scale stellar velocity dispersion of the galaxy. This is qualitatively consistent with the presence of central BHs, but raises the questions whether the excess gas dispersion is of gravitational or non-gravitational origin and whether the implied BH masses are consistent with our current understanding of BH dem ography (as predicted by the M relation between BH mass and stellar velocity dispersion). To address this we construct purely gravitational axisym m etric dynam ical m odels for the gas, both thin disk m odels and m odels with m ore general axis ratios and velocity an isotropies. For the norm algalaxies the nuclear gas dispersions are adequately reproduced assuming disks around BHs with masses that follow the M relation. In contrast, the gas dispersions observed for the radio galaxies generally exceed those predicted by any of the models. We attribute this to the presence of non-gravitational motions in the gas that are similar to or larger than the gravitational motions. The non-gravitational motions are presumably driven by the active galactic nucleus (AGN), but we do not nd a relation between the radiative output of the AGN and the nongravitational dispersion. Given the uncertainties about the dynam ical state of the gas,

it is not possible to uniquely determ ine the BH mass for each galaxy from its nuclear gas dispersion. However, for the sample as a whole the observed dispersions do not provide evidence for signi cant deviations from the M relation.

1. Introduction

The mass of a central black hole (BH) in a galaxy can be directly weighed using gravitational 'test particles' moving around it (see e.g., Korm endy & Richstone 1995). Commonly used test particles are stars, optical em ission-line gas and m aser clouds. These m ove around in the combined potential well of the stellar mass and the central black hole mass. A secure direct dynamical m easurem ent of the BH m ass requires that the distribution and kinem atics of the test particles are measured in the immediate vicinity of the BH, i.e., the 'black hole's sphere of in uence', so that its gravitational potential has a measurable e ect on the kinem atics in addition to the e ect of the stellar mass potential. G round-based optical telescopes can resolve the BH's sphere of in uence only for very nearby galaxies, with our Miky W ay being a spectacular nearby example (e.g., G hez et al. 2003; Schodelet al. 2003). The Hubble Space Telescope (HST) can provide the required spatial resolution for galaxies with distances up to several tens of M pc (e.g., K orm endy & G ebhardt 2001). The Very Long Baseline Interferom eter (VLBI) can in principle probe BH m asses out to even larger distances provided that the galaxies display nuclear m aser em ission. Together these m ethods have led to direct dynam icalm easurem ents of BH m asses M in the range M 10^6 5 10^9 M in several tens of galaxies in the nearby Universe (see e.g., Trem aine et al. 2002; Marconiet al. 2003 for listings of BH m ass m easurem ents). The BH m asses are m ostly based on dynam icalm odeling of kinem atics of either stars or em ission-line gas. The detected black hole masses M correlate well with both host spheroid lum inosity $\rm L_{B}$, global stellar velocity dispersion $~_{\rm s}$ and spheroid mass (Gebhardt et al., 2000; Ferrarese & Merritt, 2000; Trem aine et al. 2002; Marconi et al. 2003; Haring & Rix 2004). These correlations roughly represent our current know ledge of the local BH dem ography. To explore these correlations further, i.e., their scatter and extent in BH m ass, dynam icalm odeling using em ission-line gas kinem atics in early-type galaxies is convenient and in some respects even crucial. First of all, m one than 50% of the early-type galaxies in the nearby U niverse contain gas at their centers (e.g., Goudfrooijet al. 1994; Ho, Filippenko & Sargent 1997). Second of all, the most massive black holes currently found (i.e., M & 10⁹ M) are often in giant ellipticals. The central stellar surface brightness of these galaxies is typically too low to obtain accurate stellar kinem atics with HST and maser emission has not been detected (e.g., Barth et al. 2004).

At the centers of galaxies, the collisional gas is expected to settle quickly into a disk, if unperturbed by forces other than gravity (e.g., Habe & Ikeuchi 1985). The frequent detection with HST of disk-like structures in dust and gas in early-type galaxies suggests that settling actually takes place (e.g., van Dokkum & Franx 1995; Tran et al. 2001; Verdoes K leijn et al. 1999; Laine et al. 2003). Therefore the extended gas velocities in galactic nuclei have been modeled assum ing a thin disk in circular rotation. Such models have been successful in explaining the observed gas velocities. However, in the few cases where both gas velocities and gas dispersions are modeled, it is often found that the nuclear velocity dispersion exceeds the prediction for a thin disk (van der M arel & van den Bosch 1998; Barth et al. 2001; M aciejew ski & Binney 2001; C appellari et al. 2002; Verdoes K leijn et al. 2002). M any of these targets are AGN and display regular disks of dust and gas. The origin of this 'excess' velocity dispersion is unknown. Two common ad-hoc assumptions are that: (a) the excess dispersion is due to non-gravitational 'turbulent' forces of unknown origin which do not a ect the mean circular rotation of the gas (e.g., van der M arel & van den Bosch 1998; Verdoes K leijn et al. 2002); or (b) the excess dispersion is purely gravitational and a ects the rotation of the gas through the asymmetric drift equation (e.g., Barth et al. 2001).

A main aim of this paper is to determ ine which early-type galaxies do and which do not display an excess in nuclear gas dispersion. If there are galaxies for which the disk remains thin all the way to the nucleus, then any velocity dispersion observed through a nuclear aperture is caused by di erential rotation over this aperture. A nuclear aperture samples gas which is much closer to the BH than a series of apertures which samples the extended rotation curve. Hence, the nuclear gas dispersion can be sensitive to much lower black hole masses than the rotation curve. This is relevant as the sensitivity in term s of the minimum detectable BH mass in early-type galaxies with stellar dynamical methods or with gas rotation velocities is typically not much below the values predicted by the correlations between BH mass and spheroid properties. A relevant example in this case is the claim that active spiral galaxies classi ed as N arrow Line Seyfert 1s harbor BH s with masses smaller than those predicted by the M relation (e.g., G rupe & M athur 2004).

For the galaxies with nuclear gas dispersions in excess of that expected from a thin disk, we want to determ ine the origin of this excess. On the one hand, if it has a gravitational origin, this im plies that the gas should rotate less fast than the circular speed and the thin-disk approxim ation does not hold. The gas might then have a distribution somewhere in the range from a thin disk to a purely spherical distribution. Previous BH mass estimates based on the assumption of thin disks would then be underestimates, and this would a ect the observed correlations between black hole mass and large-scale spheroid properties. On the other hand, if the excess dispersion has a non-gravitational origin, we would like to quantify how it depends on galaxy parameters, such as nuclear activity. This in turn could shed light on the accretion process in these nearby, typically low-lum inosity, AGN.

In sum mary, this paper studies the nature of the line widths of emission-gas in nearby earlytype galaxy nuclei and its implications for the BH demography and BH accretion processes. A similar study into the line-widths of gas for late-type galaxies has been performed by Sarzi et al. (2002). The outline of the paper is as follows. Section 2 describes the sample selection, the data and the determ ination of the central gas velocity dispersions. Section 3 compares the observed dispersions to those expected from a thin circular disk. Section 4 compares the observed dispersions to those expected from a gas distribution which is more spheroidal than a disk. Section 5 constrains the direction of the non-gravitational dispersion. Section 6 describes the caveats of our modeling. Finally, Section 7 provides a discussion of the results and lists the main conclusions of the paper. Throughout the paper we use a Hubble constant H $_0$ = 75 km s ${}^{1}M$ pc 1 .

2. Sam ple and D ata A nalysis

We analyze a sample of 27 galaxies. It consists of galaxies which meet the following requirements: (a) early-type host morphology; (b) distance below 110 Mpc; (c) a large-scale stellar velocity dispersion m easurem ent is available from the literature; (d) HST in aging exists that shows an identi able (i.e., relatively unobscured) nucleus; (e) HST em ission line spectroscopy exists for which kinematics and ux proles were published (20 galaxies) or which are available in the HST archive (7 galaxies). We excluded galaxies for which the signal-to-noise ratio of the spectrum was very low, complicating a reliable analysis. Sixteen of the galaxies are classied as Fanaro & Riley Type I radio galaxies with jets on scales of tens of kpc or larger. The other 11 galaxies also have radio em ission. Their radio lum inosity is typically much lower (cf. Table 1) and the radio em ission originates from a central compact component. We reduced and analyzed the archival data for the 7 galaxies sim ilarly as in our previous papers (e.g., Noel-Storr et al. 2003; Verdoes K leijn et al. 2002). The spectra for all galaxies except two were obtained with HST/STIS in combination with the G 750M grating. For IC 1459 a HST /ST IS spectrum with the G 430L grating was obtained and for NGC 6251 a HST/FOS spectrum with the 0:1⁰⁰ PAIR B aperture. All spectra cover the H + NII] and [SII]6716,6731 lines, except for the G 430L spectrum of IC 1459. In that case we use the H line for our analysis. Table 1 lists basic data for the sample galaxies.

The rst step is to determ ine the gas velocity dispersions in the central region of each galaxy. In most cases (both in the literature and in our analysis of the archival spectra) single G aussian ts were m ade to each of the lines of the H + N II] composite and to the weaker [SII]6716, 6731 lines. Only in NGC 3245 and NGC 4526 are the [SII] lines too weak to be tted. For NGC 6251 we used the tto the H + N II] lines available in Fernarese & Ford (1999). For these narrow components, the N II] 6584 was the strongest line in 85% of the galaxies. In four galaxies (NGC 3245, NGC 3998, NGC 4278 and NGC 6251) a broad em ission-line component is clearly present in addition to the narrow H + N II] components. This is most likely due to a broad H component because the broad component is not seen in the [SII] forbidden lines and the forbidden N II] lines originate presum ably in the same region as the [SII] lines. This broad component was tted with an additional G aussian. For the two archival sources with a broad component (NGC 3998 and NGC 4278) we established that the [SII] lines provide an important tting constraint in addition to the H + N II] region which is blended heavily due to the broad component. Excluding the [SII] doublet from the t results in

35% larger (NGC 3998) or smaller (NGC 4278) dispersion. Similarly, Ferrarese & Ford (1999) report for NGC 6251 a width of the [SII] lines which is 37% larger than the H + [NII] lines at the nuclear aperture. For the archival cases with only narrow lines, we determ ined that the inferred gas dispersion changes by . 10% by excluding the [SII] doublet from the t.

The next step is to nd for each galaxy the aperture closest to the nucleus which we will refer to as the 'central' aperture. We assume that the dynam ical nucleus coincides with the peak in emission-line and continuum ux. The typical dimension of the ST IS apertures is $0.1^{\circ0} \quad 0.2^{\circ0}$ in the spectral direction and $0.05^{\circ0} \quad 0.1^{\circ0}$ in the spatial direction (see Table 2). The exact sub-pixel location along the slit of the nucleus was determined by tting a Gaussian to the central few emission-line uxes. In most cases the peak in velocity dispersion coincides with the ux peak. We indicate in Table 1 the few cases in which the maximum dispersion does not peak at the central aperture but just outside it. The exact location of the nucleus (i.e., the ux peak under our assumptions) in the direction of the slit width is not known. We assume that it is centrally located in this direction. This seems plausible given that the target acquisition procedure is designed to have the center of the slit located exactly on the brightest continuum point in the galaxy. That this 'peak-up' procedure actually succeeded is supported by the steep decline in ux in parallel slits which are available for m any targets. Nevertheless, the e ect on our results of a potential o -set from this location is discussed in Section 6. The gas velocity dispersion $_{g}$ at the central aperture is listed in Table 1. The typical relative form alm easurement error for $_{g}$ is 5%.

We also require the unconvolved ux prole for our analysis. The emission-line surface brightness is represented by tting a double exponential function,

$$I(R) = I_1 \exp(R = R_1) + I_2 \exp(R = R_2);$$
 (1)

to the narrow emission-line uxes taking into account the PSF and disk inclination (see e.g., Verdoes K leijn et al. 2002 for a detailed description). The disk inclinations were taken from the literature or determ ined by us from the extended dust disk often present on HST in aging. If dust is absent or the inclination could not be determ ined reliably, we assumed i = 60. The HST observational characteristics, unconvolved ux pro les and disk inclinations are listed in Table 2. The uxes are typically tted within the form all errors or within 10%. A few galaxies have some asymmetry in their pro les over which the symmetric t averages, namely IC 1459, NGC 3245, NGC 4278, NGC 4459 and NGC 4486.

Finally, we use published stellar dispersions (see Table 1). The stellar dispersions $_{\rm s}$ are measured through an aperture of typically several arcsec². This corresponds to a region much larger than the BH sphere of in uence, and measures primarily the virial dispersion of the system as a whole. We will make use of the stellar dispersions to estimate black hole masses using the M relation as determined by Tremaine et al. (2002). The relation is calibrated to ux-weighted stellar dispersions $_{\rm e}$ inside an elective radius of the galaxy, which are not available for most of our sample galaxies. However, comparing $_{\rm e}$ and $_{\rm s}$ where possible shows a difference of typically

7% between $_{\rm s}$ and $_{\rm e}$. We will use this as the typical relative error on our m easurement of $_{\rm s}$ in approximation to $_{\rm e}$. Lastly, Table 1 also lists the black hole masses obtained from dynamical modeling of central gas disk rotation velocities as published for eight galaxies in the sample.

3. Thin Disk Models

Figure 1 shows the central gas velocity dispersion at small scales (i.e., typical aperture size $0.15^{\circ\circ}$ or $40 \,\mathrm{pc}$ for typical galaxy distance of $50 \,\mathrm{M}\,\mathrm{pc}$) versus the large-scale stellar dispersions (tracing the ux-weighted dispersion at kpc scales). The nuclear gas dispersions are almost always larger than the large-scale stellar dispersions, increasingly so for larger stellar dispersions. G iven the success rate of black hole mass determ inations in early-type galaxies, it now seems quite possible that all spheroids harbor a black hole at their nucleus. There are two generic ways in which the presence of a BH can contribute to the nuclear gas dispersion. First, gas motions increase at smaller distances from a central black hole due to the increase of the gravitational force. Integrated over a

nite aperture this will lead to a larger observed gas dispersion. We will call this the gravitational contribution. A n increase will occur always, but its magnitude will depend on the physical structure and orbital distribution of the gas, e.g., a thin rotating disk or a more spheroidal distribution. The e ect is noticeable because for a typical $_{s}$ = 250 km s¹ in our sample, the typical central HST aperture is only a factor two larger than the rough measure of the black hole radius of in uence $r_{BH} = GM = \frac{2}{S}$ 20 pc adopting the M relation from Trem aine et al. (2002). The relation 4. If the gas motions are dominated by gravitation it is expected that nds M , with $^2_{
m s}$ qualitatively consistent with the increasing ratio of $_{
m g}$ and _q with 2 and hence _q М s shown in Figure 1. The M relation also suggests that one should expect a sm aller excess gas dispersion in galaxies with sm aller s for another reason: galaxies with sm all s have a sm aller BH m ass and a sphere of in uence so that a ST IS aperture of xed size sam ples m ore of the gas outside of the BH sphere of in uence. A second generic way in which the presence of a BH can contribute to the nuclear gas dispersion is not through its gravitational force, but through input of kinetic energy which perturbs the collisional gas. We will call this the hydrodynam ical or non-gravitational contribution. This energy could be released by processes related to an active black hole. As a side rem ark, it is unlikely that the kinetic energy m ight be provided by collisions with photons emerging from the active region around the black hole. The reason is that the bolom etric lum inosity of the low-lum inosity active nuclei discussed here is always orders of magnitudes below the Eddington lum inosity (e.g., Ho 1999). Shocks, e.g., jet-gas interactions are a more plausible source of kinetic energy. It could be that the gravitational contribution dom inates (e.g., a thin disk of non-colliding gas particles in circular rotation) or that the hydrodynam ical contribution dom inates (e.g., a fully collisionally driven out ow of gas from the active black hole). The well-de ned thin dust and gas disks often seen in mediately outside the nucleus in these galaxies suggest that the gas might be settled all the way to the nucleus. Therefore, we will st determ ine the answer to the question: in

The answer to this question is known already for ve galaxies in our sample for which detailed m odeling has been perform ed of both gas velocities and dispersions of the extended gas disk under the assumption of a thin circular disk. In the case of NGC 7052 (van der M arel & van den B osch 1998), IC 1459 (C appellari et al. 2002; Verdoes K leijn et al. 1999) and NGC 4335 (Verdoes K leijn et al. 2002), an excess of dispersion by a factor 2 or m ore was observed. For NGC 3245 (B arth et al. 2001), a smaller excess of 35% was observed. In the case of M 87 (M acchetto et al. 1997; H arm s et al. 1994), no dispersion excess was observed. The velocity dispersion for this galaxy was accounted for by a m odel in which the gas resides in an annulus instead of a disk. (T his m odel can also account well for the velocities and peculiarities in the ux distribution.) It is these m ixed results on excess gas dispersion that lead us to exam ine the presence of excess gas dispersion for a larger sam ple of galaxies.

which galaxies can the BH potential account for the observed nuclear gas dispersion assum ing that

the gas is located in a thin circular disk?

In the present and following sections (Section 3(5) we present results of dynamical models of the gas velocity dispersions. C aveats that result from the assumptions in our models are discussed in Section 6. Performing gas disk kinematical modeling for our complete sample in similar detail as done for the aforementioned few cases is beyond the scope of this paper. Thus we constructed som ew hat more simplied thin disk models. The main simplication is to neglect the stellar mass contribution to the central gravitational potential. The e ect of this simplication on the predicted velocity dispersions for the galaxy sample can be estimated as follows. A sum e a spherical stellar mass density $(r) = _0 (r=r_0)$ in the nuclear region, where r is the radius in pc and $_0$ a scaling constant. A coording to the LEDA database, the absolute blue magnitude in our sample varies in the range M_B = [19:3; 22:5] with a mean < M_B >= 21:1. A sum ing a typical galaxy color B V = 0:95, this indicates that a typical galaxy in our sample is about 1 m agnitude brighter than the division magnitude at M_V 21:0 between shallow core and steep core (\power-law")) galaxies (G ebhardt et al. 1996). G alaxies brighter than this division magnitude typically have

1 (while below they have 2). From the study by Gebhardt et al. (1996) we infer a typical $_{\rm 0}$. 10^4 M $~=\!pc^3.$ W ith this information we can compute the circular velocity $v_{c;s}$ due to the stellar mass at a given radius as $v_{c,s}^2 = 4 G_0 \frac{r^{+2}}{+3}$. By comparison, the circular velocity due to the BH is $v_{c;BH}^2 = \frac{GM}{r}$. We compute the ratio of these two at $r = 0.1^{00}$ from the nucleus assuming a BH mass according to the M relation. The value $r = 0.1^{00}$ is a typical distance from the galaxy center at which we have measured gas dispersions with HST. The ratio of the circular velocities in quadrature (i.e., equivalent to the ratio in dynam ical mass) is always less than 20%. This is much smaller than, e.g., the scatter of 0:3 dex in the M relation (Trem aine et al. 2002). This con m s that the stellar m ass contribution in our analysis can be safely neglected, provided that: (a) the BH m asses are not signi cantly below the M relation; and (b) we are 0:1⁰⁰. A s an not attempting to model the large scale rotation of the gas at radii much beyond additional check we directly determ ined the di erence in predicted dispersion with and without BH mass for NGC 4335, NGC 7052 and IC 1459. For these galaxies, we modeled the stellar mass in previous papers (Verdoes K lein et al. 2002; van der M arel & van den B osch 1998; Verdoes K lein et al. 1999). These cases con im the result from the general argum ent that the di erence in predicted dynam ical m asses is always less than 20% (see also F igure 2, discussed below).

For a thin circular disk, the velocity dispersion observed in a nuclear aperture is due entirely to di erential rotation over the aperture. To calculate this dispersion we used the modeling software that is described in more detail in van der Marel & van den Bosch (1998) and Verdoes K lein et al. (2000; 2002). This modeling takes into account the emission-line ux prole, slit width and PSF convolution. We rstm odeled the galaxies for which a BH m assestim ate is available in the literature from detailed modeling of the gas rotation velocities. Figure 2 shows the predicted versus observed velocity dispersions for these eight galaxies. Seven galaxies have an observed dispersion in excess of the prediction. The modeling nicely reproduces the aforem entioned relative di erences in excess dispersion for M 87, NGC 3245, NGC 7052, NGC 4335 and IC 1459 known from prior m odeling of the rotation velocities in the extended gas disk. To put the complete sample in a similar diagram, we need an estim ate of the BH m ass for every galaxy. For this we use the M relation as calibrated by Trem aine et al. (2002). They derive the relation $\log M$ (M)] = 8:13 + 4:02 log (=200 km s⁻¹). The slope of this relation falls between those reported by Gebhardt et al. (2000; slop = 3.75) and Ferrarese & Merritt (2000; slope= 5.27). Figure 3 shows the predicted versus observed dispersion for a thin disk m odel, but now assuming for all galaxies a BH m ass according to the M relation. The observed dispersions in non-radio galaxies scatter around the prediction from the model (except for IC 989: cf. Section 7). In fact, the number of non-radio galaxies and their range in observed gas dispersions is large enough that they independently con m the M relation for the thin

disk model. This is non-trivial because BH masses signi cantly below the M relation could have been detected with the HST/STIS observations. As a measure of the minimally detectable BH mass, we compute the BH mass which causes a gas dispersion which equals that predicted from the combined e ect of instrum ental broadening and the stellar mass model discussed above. W e use again the typical radius of $0:1^{10}$ and take into account the disk inclination and distance for each galaxy. The resulting masses vary between 6 10⁶ M and $6 10^7 \,\mathrm{M}$ with a typical value of $3 10^7 \,\mathrm{M}$. (Exceptions are NGC 3862 and UGC 7115. Their m inim ally detectable BH mass lies above the M relation because the instrum ental line broadening is larger than the dispersion due to di erential gravitational rotation for such close to face-on gas disks.) The BH masses predicted by the M relation exceed this typical detectable BH mass by a factor 2 for the lowest stellar dispersions and by alm ost 2 orders of magnitude for the highest stellar dispersions in the sample. In conclusion, the gas dispersions in non-radio galaxies support the idea

dispersions in the sample. In conclusion, the gas dispersions in non-radio galaxies support the idea that all early-type galaxies harbor supermassive black holes at their nuclei with masses according to the M relation.

In contrast to the non-radio galaxies, all radio galaxies have a gas dispersion in excess of that expected from the thin disk models. About 50% of those fall above the 1 scatter expected from the intrinsic scatter in the M relation. To explore the origin of this we plot in Figure 4 the ratio R_{ord} of observed dispersion and that predicted for the disk model. There is a trend of an increasing ratio with decreasing disk inclination. In fact, the four largest ratios are all in galaxies with gas disk inclinations i < 40, i.e., close to face-on disks. This cannot be explained as a result of measurement errors in the dust disk inclinations. The arrows in Figure 4 show by how much R_{od} can decrease due to the known m easurem ents errors. The decreases do not change the overall result that radio galaxies system atically have excess dispersions. A more extrem e (and probably unphysical) possibility is to assume that we might have used incorrect inclinations because the m easured dust disk inclinations bear no relation to the actual inner gas disk inclinations. However, this would still not provide a satisfactory explanation. If all the gas disks were in reality edge-on and well described by thin disk models, then we would have expected the points in Figure 4 to fall. along the curve $R_{oxt} = \sin^{-1} i$ (solid curve). This still falls below many of the observed dispersion ratios (see Figure 4). Moreover, an excess gas dispersion is not only seen in radio galaxies with relatively face-on disks. If we exlude system s with disk inclinations i < 40 from the analysis, the m edian $R_{ord} = 1.32$ for radio galaxies versus 0.96 for non-radio galaxies. A m edian test yields a probability of only 0.05 that this di errence would occur by chance in the event that the sam ples were drawn from populations with the same median. Therefore, a solution to account for the excess gas dispersion in radio galaxies must probably be sought in having a signi cant vertical velocity dispersion com ponent.

Finally, as a sanity check we analyzed the dependence of the R_{ord} on BH m ass and the typical circular velocity of the system, parameterized as $\frac{GM}{r_{HALF}}$ where r_{HALF} is the radius inside which half of the light of the unconvolved emission-line ux distribution is contained. There is no relation between the dispersion ratio and the two m easures of the gravitational potential. This con rm s that the excess velocity dispersion in the radio galaxies is not somehow an artifact of our gravitational modeling.

4. Spheroidal M odels

M any galaxies in the sample show disks of dust and gas with radii ranging from hundreds of pc up to several kpcs. It appears reasonable, but m ight be wrong to assume by extrapolation that the nuclear region within the spatial resolution of the observations also has a disk-like geometry. Instead, the gas distribution m ight be more spheroidal in the vicinity of the black hole. In that case the gas moves also out of the plane of the larger scale thin gas disk. This could explain qualitatively the observed increasing ratio of observed versus predicted dispersion for decreasing dust disk inclination. We address next whether such a spheroidal distribution can also quantitatively explain the observed of gravitationally.

G as in a vertically extended distribution (e.g., a spherical one) tends to collapse quickly to a disk due to hydrodynam ical forces. Thus, to maintain a spheroidal structure, one would have to assume that the gas is located in individual clouds that move collisionlessly. As an initial assessment of the plausibility of this we estimate the collision time-scale for clouds in a simplistic model: spherical cloudlets of ionized hydrogen moving around in a spherical volume. The typical time t_{free} between cloudlet collisions is estimated as:

$$t_{\rm free} = \frac{V}{N_{\rm cl}} \frac{1}{v_{\rm cl}};$$
(2)

where v_{cl} is the typical relative velocity of cloudlets, V is the spherical volume within which the cloudlets are contained, _{cl} is the cross-section of each cloudlet and N_{cl} is the total number of clouds. For V we take the spherical volume with a radius equal to the half-light radius of the gas distribution as seen projected on the sky. For v_{cl} we take the circular velocity at half the half-light radius. The number of cloudlets N_{cl} is computed from

$$N_{cl} = N = (\frac{4}{3} R_{cl}^{3} n_{e});$$
 (3)

where N is the total number of electrons, n_e is the electron density and R_{cl} is the radius of each cloudlet. The electron density can be obtained from the relation between the ux ratio [SII] 6716/ 6731 and the electron density (O sterbrock 1989). This ux ratio is only sensitive to electron densities in the range $[10^2;10^4]$ cm ³. Outside this range the ux ratio becomes constant as a function of n_e . We obtain the ux ratio for 15 of the radio galaxies from Noel-Storr et al. (2003) of which six lead to upper and lower-limits on the electron density. N can be estimated as discussed in O sterbrock (1989) assuming case B recombination:

$$N = \frac{L_{H}}{n_{e} H_{H}^{eff} h_{H}}; \qquad (4)$$

where $_{\rm H}^{\rm eff}$ = 3.03 10 ¹⁴ cm ³ is the recombination coe cient (assuming T = 10 ⁴K) and _H and L_H are the frequency and luminosity for H . We obtain L_H from the central H + [N II] luminosity (Verdoes K leiph et al. 2002) using the standard L_H =L_H ratio of 3.1 and the [N II] 6548,6584 / H ux ratio determined from our G aussian line ts. This results in the following equation for the collision time:

$$t_{\text{free}} \quad \frac{\frac{R^{35}n_e^2 R_{cl}}{M_{L_H}}}{M_{L_H}} \tag{5}$$

This increases linearly with the radius of the cloudlets R_{cl} . If we assume that R_{cl} is as large as a tenth of the half-light radius, then the inferred t_{free} varies between 10^3 yr and 10^{13} yr with a typical value of 10^7 ⁸yr. Some of the huge scatter is most likely due to the sim plicity of the estimate. But either way, it appears unlikely that the gas could remain in a collisionless state for a signi cant fraction of the Hubble time. Collisions lead to dissipation, loss of energy, and settling onto circular orbits. However, this only true if there is no energy input into the gas. That may well be incorrect for most of the galaxies in our sample, given that 16 galaxies are FR I radio galaxies, and the remainder have nuclear radio emission. If there is energy input, then the gas can maintain an extended distribution for much longer than the timescale t_{free} calculated above. Even though collisions would occur, one might expect the system to evolve through a sequence of states that are all approximately collisionless. Therefore, it is reasonable to study the predictions of collisionless m odels for the nuclear gas in our sample galaxies.

A major uncertainty in the calculation of collisionless models is the phase-space distribution of the clouds, which is needed to compute the observed velocity dispersion along the line of sight. The phase-space distribution involves a spatial component such as a radial number density pro le. We do not know this pro le. We only know the ux distribution, which could be quite di erent. The phase-space distribution also requires know ledge about the nature of the cloud kinem atics, for example anisotropies in the velocity dispersion. These are also unknown. We therefore decided to explore the line-of-sight velocity dispersion for a plausible range of phase-space distributions. We use axisym m etric dynam ical m odels presented in de Bruijne et al. (1996). W e explore gas clouds with an axisymmetric power-law number density distribution with axis ratio q (i.e., (R;z) = $_{0}\mathbb{R}^{2} + z^{2} = q^{2}$ (=2)]) in the K epler potential caused by the black hole. The gas clouds are assumed to have a constant velocity dispersion an isotropy = 1 $(\sqrt{2} + \sqrt{2}) = (2\sqrt{2})$ (i.e., the 'case II' models' in de Bruijne et al. 1996; cf. Binney 1980, with (r; ;) the usual spherical coordinates). Thus we have four free param eters: the num ber density scaling constant 0, the axis ratio q, the power-law slope of the particle density pro le and the velocity dispersion an isotropy . These models require to be physical. De Bruine et al. (1995) evaluated the projected velocity dispersions. > 1=2 + The software to calculate them num erically is available from http://www.stsciedu/ marel/.

W e want to know how di erent the observed velocity dispersion for a spheroid can be com pared to the dispersion for a thin disk, for a plausible range of the free parameters. Thus we determ ined the ratio $R_{s;d}$ of the velocity dispersions for a spheroid and a thin disk that have the same projected surface density distribution and apparent axial ratio. The latter criterion xes the ratio of the $_0$ values for the two models, and im plies that $R_{s;d}$ is independent of $_0$. We de ne $R_{s;d}$ as the ratio of the line-of-sight dispersion weighted by the num ber density and integrated over an aperture which is typical for the observations. The result depends on power-law slope, axis ratio and dispersion anisotropy. We explored the parameter ranges = [1:5; 10], q = [0:1;0:9] and = [inf;1], which should encom pass all plausible models. Figure 5 shows $R_{s;d}$ as a function of apparent axis ratio for the quoted parameters ranges. Regardless of the choice of parameters, the modeled spheroidal distributions have increased velocity dispersions in comparison to thin disks only for q & 0:7 (corresponding to inclinations i. 45 for a thin disk).

As also shown in Figure 4, the non-radio galaxies scatter around $R_{ord} = 1$ indicating that their dispersions are consistent with thin disks in circular rotation around BHs that follow the M

relation. By contrast, the radio galaxies have dispersion ratios $R_{o,d}$ which are system atically larger than 1, and also larger than the $R_{s,d}$ expected for collisionless spheroidal models. So it seems unlikely that a spheroidal distribution of collisionless gas clouds can account for the nuclear gas velocity dispersions in radio galaxies. We also explored the ratio of the velocity dispersions for an axisym metric spheroid and a disk at the same inclination instead of the same apparent axis ratio¹. The reason is that the axis ratio of the gas distribution at the nucleus is not constrained very well by the observations and might deviate from the axis ratio of the larger scale disk. The resulting $R_{s,d}$ range for spheroid models at a given inclination remains very similar. So this does not alter the conclusions inferred from Figures 4 and 5.

5. The non-gravitational gas dispersion component

The analysis of thin disks and spheroidalm odels indicates that non-gravitational forces m ight contribute signi cantly to the observed gas dispersion for radio galaxies. To constrain the m inim al relative contribution of a non-gravitational dispersion component we plot in the top panelofF igure 6 the ratio of the observed dispersion and them axim um dispersion predicted by either disk or spheroid m odels. The m inim al ratio is typically between 1 and 2. There is a hint that the m inim al ratio increases with axial ratio, i.e., for extended disks that are closer to face-on. This could indicate that the non-gravitational dispersion component does not have a random orientation with respect to the extended disk but is oriented preferentially along the spin axis of the extended disk. We explore this idea with two simple m odels. The m odels consist of two components: a thin circular rotating disk and a second component of non-gravitational m otions. We assume equal contribution to the em ission-light by the two components. In the 'isotropic m odel' the non-gravitational dispersion is isotropic ($_{iso}$) and the resulting total dispersion can be written as

$${}^{2}_{\text{obs}} = {}^{2}_{\text{grav}} \sin^{2} i + {}^{2}_{iso} = 3;$$
 (6)

where grav denotes the dispersion due to circular rotation as measured in the plane of the disk and i is the disk inclination. In the 'perpendicular model' the non-gravitational dispersion is assumed to be perpendicular to the plane of the disk:

$${}^{2}_{\text{obs}} = {}^{2}_{\text{grav}} \sin^{2} i + {}^{2}_{\text{perp}} \cos^{2} i;$$
(7)

The middle and bottom panels of Figure 6 show the ratios $_{iso} = _{grav}$ and $_{perp} = _{grav}$ as a function of disk axis ratio. The value of $_{grav}$ is calculated as before from the thin disk models and $_{iso}$ and $_{perp}$, respectively, are chosen so that $_{obs}$ matches the observed value $_{g}$. The perpendicular model shows no trend between the dispersion ratio and disk inclination. The isotropic model shows a weak trend. This would not be expected in an isotropic scenario. On the other hand, the trend in Figure 6b is dom inated by a few galaxies and is not really signi cant. For some galaxies the in plied non-gravitational dispersion is larger than $\frac{1}{2} g_{grav}$. In other words, the typical non-gravitational motions are larger than $\frac{1}{2}$ times the typical circular rotation in those galaxies which suggests that

 $^{^1}$ N ote that in this case that the disk and spheroid do not have an identical surface density distribution.

some of the material might be unbound. However, the models are too simplistic to attach real signi cance to this result.

The fact that radio galaxies show an excess gas dispersion, while it appears to be absent in non-radio galaxies, possibly points to a link between non-gravitational motion and activity. The AGN could be a source of energy to drive the non-gravitational dispersion e.g., by coherent ow sor turbulence. We do not have a direct measure of the kinetic energy output of the AGN to determ ine its correlation with the am ount of non-gravitational dispersion present in the gas. Thus we resort to measures of the radiative energy output of the active nuclei as a proxy. Figure 7 shows R_{ord} as a function of total radio power for both radio and non-radio galaxies. As expected, the di erence in excess dispersion for non-radio and radio galaxies is also present as a function of radio lum inosity. How ever, there is no clear indication that larger non-gravitational motions occur in more pow erful radio galaxies. We exam ined also the dependence of R_{ord} on radio core and nuclear emission-line lum inosity for radio galaxies. No clear trends were found. Sim ilarly, no trends were found between the ratios $_{iso} = _{grav}$ and $_{perp} = _{grav}$ with these three indicators of the radiative power of the active nucleus.

6. C aveats

Uncertainties in the ux proles For three galaxies in our sample, NGC 3862, NGC 4374 and NGC 4486, we have both the STIS ux proles and those derived from HST/W FPC2PC-chip emission-line images which are available to us. The PC pixel size ($0.045^{(0)}$) better samples the HST PSF FW HM ($0.1^{(0)}$) compared to the STIS apertures. From the PC emission-line image, a narrower ux prole is inferred for NGC 3862 and NGC 4374, but a wider prole for NGC 4486, as compared to the ux proles derived from the STIS data. Using the PC proles in the thin disk modeling leads to increases in predicted gas velocity dispersion of 5%, 50% and 13% for NGC 3862, NGC 4374 and NGC 4486, respectively. A ssum ing that similar changes could be expected for the other sample galaxies, this does not change our conclusions.

A nother possibility to consider is that we m ight have system atically overestim ated the width of the emission-line ux proles. If the ux in reality originates closer to the nucleus then in our models, it would naturally explain why the predicted dispersions are lower than observed. Figure 8 shows the radius inside which half of the ux from the intrinsic (i.e., unconvolved) ux prole is contained as a function of distance. The top panel shows the angular half light radius. For half light radii much less than the half light radius of the HST PSF, i.e., $0.05^{\circ0}$, it could well be that the intrinsic ux prole is in fact much narrower. Thus, the prole widths for NGC 2329, NGC 3862 and NGC 6251 should be considered upper limits. This im plies that their predicted velocity dispersions should be considered lower limits as emission-line gas might be rotating closer to the black hole than in our models. However, there are two facts that argue against a general overestim ate of the width of the ux proles for all galaxies. First, we nd no trend of narrower emission-line ux proles with increasing dispersion ratios. Second, such a scenario cannot explain the correlation between disk inclination and dispersion ratio. A separate question is whether we are resolving the ux prole at larger distances as well as nearby. This issue is relevant for com paring the properties of the radio galaxies and non-radio galaxies, since the form er sample has a larger average distance. The bottom panel of Figure 8 suggests that this distance o set is not inducing the di erence in excess dispersion, since there is no trend between the physical half light radius and distance.

Finally, what kind of emission-line ux prole is needed to obtain the observed gas velocity dispersions gravitationally? To rst approximation $\frac{2}{g}$ M =R _{ux}, where R _{ux} is the typical radius of the ux prole (e.g., the half light radius). Figure 4 shows that for radio galaxies R _{ux} needs to decrease by a factor of about 2 up to 100 to have a model with a black hole mass according to the M relation account for the observed gas dispersion. Figure 8 shows that the emission-line ux prole for radio galaxies typically has a half light radius which is 2 times the radius of the PSF. In conclusion, the emission-line prole for radio galaxies needs to be fully unresolved in general to account for the observed gas velocity dispersion gravitationally. This is ruled out by the observations.

Uncertainties in the location of the black hole The spatial ux distribution in the direction of the slit length allows us to precisely locate the nucleus along this direction (assuming it coincides with the peak of the emission-line ux, cf. Section 2). But the nucleus was assumed to be at the center of the slit in the direction of the slit width. This is a reasonable assumption (see Section 2). We determined that a 0.05^{00} displacement in this direction changes the predicted velocity dispersion by < 20% for the thin disk models. This does not a ect our conclusions.

relation underestim ate BH m asses? One m ight account for the ex-Does the M cess gas dispersion within the purely gravitational models, seen particularly for radio galaxies, by assuming that the BH mass from the M relation underestim ates the true BH m ass. However, this requires increases in BH masses that are too large to be credible for the following reasons. First, com parison of Figure 2 and 3 shows that detailed estimates of BH masses from gas rotation velocity modeling do not show any indication for BH masses that are system atically larger than those inferred from the M relation. (This is a som ew hat circular argum ent as som e of the BH m ass m easurem ents from gas were used to determ ine the M relation. Nevertheless, such large BH masses would imply velocity gradients which are larger than observed.) Second, the trend of an increasing R ord with decreasing disk inclination is not expected if the excess dispersion is due to underestim ated BH m asses. The dependence of BH m asson stellar dispersion is som etim es claim ed to be steeper than used here (e.g., Ferrarese 2002). However, this amounts to at most 50% larger BH masses and such uncertainties will not a ect our results on excess gas dispersions. Lastly, it has been argued that M correlates equally well with host lum inosity as with (e.g., Marconi& Hunt 2002). Thism ight mean that the M relation underestim ates M at the high end. The reason is that Brightest Cluster Galaxies (BCGs) fall in this region. The BCGs are exceedingly lum inous for their stellar dispersion which is typically above 270 km s¹ (Fisher, Illingworth & Franx 1995). If true, it is very unlikely that this will a ect our results because the galaxies in our sample with the largest excess in stellar dispersion com pared to gravitational models all have stellar dispersions between 190 km s 1 and 270 km s 1 (cf., Figure 9).

A re thin disk m odels plausible? It was found that for most of the norm algalaxies in our sample the nuclear gas dispersions are reasonably well t by thin disk m odels containing BHs that

follow the M relation. But the fullem ission lines shapes contain additional information on the line of sight velocity distribution (LOSVD) and can further constrain the plausibility of the models. We used the thin disk models to calculate the full LOSVD for the normal galaxies in the sample. Inspection of the data shows a qualitative agreement between predicted and observed LOSVDs. A general property of the LOSVD of thin disk models is a tendency for being double-peaked. In some cases the predicted double peakedness seems slightly too pronounced to be consistent with the data. But it is possible that the predicted peaks have in reality been broadened away by additional velocity dispersion contributions. For example, the gas could be collisionless but orbit in a som ew hat more three-dimensional distribution than a disk (as in the models of Section 4), or it could have a small additional non-gravitational contribution (as in the models of Section 5). O verall, the signal-to-noise ratio of the data and the blending of the H + [N II] lines make it di cult to draw strong conclusions from the observed line shapes.

Could an unaccounted broad H component in radio galaxies in uence our results? The ux from which the velocity dispersions are measured is usually dom inated by the ux from the forbidden [N II] and [S II] lines, especially the [N II] 6584 line and not the H line. Furtherm ore, we ensured to correct for the presence of broad H if it was clearly detected. This broad component is likely arising from a broad-line region which is located much closer to the nucleus than the narrow component that we model here. Noel-Storr et al. (2003) found tentative indications that a broad line, not readily seen by eye, could be present in eight of the radio galaxies in our sam ple (Table 1). In these cases they perform ed ts to the H + [N II], [SII] com plex assuming the permittedH line has both a narrow and a broad component. We redid the thin disk modeling for these eight galaxies taking into account the tentative broad component in measuring the velocity dispersion and emission-line pro le of the narrow component. This resulted in decreases of R_{ord} by at most 20% and a median decrease of 9%. Thus these eight galaxies do not change the overall results obtained together with the 13 other radio galaxies. Lastly, the dispersion in the extended disk are in m any radio galaxies above those expected from instrum entale ects and di erential rotation over the aperture (e.g., Noel-Storr et al. 2003). This strengthens the idea that the excess dispersions are not due to a nuclear broad line region.

G aussian t versus true second velocity m om ent. For the thin disk m odels we com pared the predicted second m om ent of a G aussian t to the full line of sight velocity distribution (LO SVD) to the observed G aussian t. By contrast, in the analysis of m ore spheroidal distributions, $R_{s;d}$ is the ratio of the true second m om ents. Thus we assume that the ratio of the true second m om ents and the ratio of the G aussian - t m om ents do not di er signi cantly. It is not straightforward to test this assumption quantitatively, since the line proles are not straightforward to calculate for the spheroidal models. However, we believe that the errors thus introduced are unlikely to exceed several tens of percent (van der M arel & Franx 1993). This is insu cient to a ect any of our conclusions. A lso, it seems unlikely that a di erence in these ratios would a ect our m ain result that there is a system atic di erence in nuclear dispersions between radio and non-radio galaxies.

D ependence of the stellar dispersion on inclination. In our models we have assumed that the BH mass is uniquely determined by the stellar velocity dispersion. However, this can only be approximately true in reality. There must be some intrincic scatter in the M relation, if only because the observed velocity dispersion of a galaxy generally depends on the inclination under which the galaxy is viewed, whereas the BH m ass does not. This could be important in the context of our results. The four galaxies for which thin disks models t the observed gas dispersions m ost poorly have below -average inclinations, in addition to being radio galaxies (see F igure 3). It is therefore important to study the relation between between stellar velocity dispersion and inclination in som e m ore detail.

To support its shape, an oblate stellar system must on average have more pressure (²) parallel to the equatorial plane ($\frac{2}{k}$ $\sqrt{v^2} + \sqrt{v^2_R} = 2$) than perpendicular to it ($\frac{2}{2}$ $\sqrt{v^2_z}$). Therefore, it will generally have a lower line-of-sight velocity dispersion when viewed face-on than when viewed edge-on. The tensor virial theorem (B inney & Trem aine 1986) gives the ratio of the pressures when integrated over the entire galaxy as

$$(_{k} = _{?})^{2} = \frac{1}{2} \frac{p \frac{1}{1 e^{2}} \frac{\operatorname{arcsin} e}{e}}{1 p \frac{1}{1 e^{2}} \frac{\operatorname{arcsin} e}{e}}; e^{2} 1 q_{t}^{2}:$$
 (8)

where $q_{\rm L}$ is the intrinsic axial ratio. For example, this gives $_{\rm k}=_{?}=1$ for a spherical galaxy and $_{\rm k}=_{?}=1:34$ for a galaxy with q=0.5. If one were to observe a galaxy with an aperture of in nite size, and if the galaxy had $\overline{v^2}=\overline{v_{\rm R}^2}$ at all positions in the galaxy, then the ratio of the measured dispersion when viewed edge-on and face-on, respectively, would be equal to $_{\rm k}=_{?}$. However, these requirements are not generally met for real galaxies and real observations. There is no reason why galaxies should have $\overline{v^2}=\overline{v_{\rm R}^2}=1$, and observational constraints on this ratio remain scarce (e.g., G ebhardt et al. 2003). A loo, velocity dispersion measurements are generally restricted to the central region of the galaxy and/or a speci c axis (most offen the major axis) and do not integrate over the entire galaxy. So the true dependence of the observed stellar velocity dispersion on the inclination angle can only be addressed with detailed three-integral stellar dynamical models (e.g., G ebhardt et al. 2003; C appellari et al. 2005b), which are outside the scope of the present work. N onetheless, the tensor virial theorem does provide useful order-ofm agnitude guidance. A lm ost all elliptical galaxies have axial ratios q > 0.5 (Franx, Illingworth & de Zeeuw 1991; Trem blay & M erritt 1995). Therefore, one might expect that inclination e ects cause a variation of order 15% (0.06 dex) in the observed velocity dispersion of galaxies of otherwise identical properties.

A n alternative way to constrain the inclination dependence of the velocity dispersion is through the scatter in several well-know relations. The velocity dispersions correlates strongly with galaxy lum inosity (the Faber-Jackson relation; e.g., D ressler et al. 1987), with BH m ass (the M relation), and with galaxy m ass-to-light ratio M =L (C appellari et al. 2005b). None of the latter quantities depends on the view ing angle of the observations, while the velocity dispersion does. Therefore, the observed scatter in these relations sets an upper limit to the RM S variation that the inclination m ight induce in the observed velocity dispersion. The limits are 0.25=3.50 = 0.072dex from the Faber-Jackson relation (D ressler et al. 1987), 0.30=4.02 = 0.075 dex from the M relation (T remaine et al. 2002), and 0.07=0.82 = 0.083 dex from the relation with M =L (C appellari et al. 2005b). These results are all in reasonable agreement with the expectation from the virial theorem (despite the fact that each of these relations is likely to have other sources of intrinsic scatter as well). Lastly, direct estimates of the dispersion anisotropy in giant ellipticals from detailed threeintegral stellar dynam ical m odels indicate a change of 0.05 dex in stellar dispersion for face-on and edge-on viewing angles (Cappellari et al. 2005a). Given that rotational velocities contribute typically less than 10% to the second moment of giant ellipticals this lends further support for the estimates based on global relations for the dependence of the stellar dispersion on inclination.

To obtain more spec c information for the actual galaxies in our sample we plot their Faber-Jackson relation in Figure 9. The four galaxies with dust/gas disk inclinations i < 40 are indicated with special symbols. If the disks reside in the equatorial plane of the galaxies, then the disk inclinations are identical to the galaxy inclinations. One would then expect the galaxies with i < 40 to have relatively low stellar velocity dispersions for their lum inosity. This is exactly what the gure shows. The galaxies with i < 40 seem to lie 17% (0:079 dex) below the average relation between galaxy magnitude and stellar dispersion. This agrees to low est order with the expectation from the tensor virial theorem and the scatter in well-known correlations.

So there is theoretical and observational support for the idea that the observed stellar velocity dispersion depends on the galaxy inclination angle. By using the M relation to estimate the BH mass one is therefore likely to underestimate the BH mass of galaxies with relatively low inclinations. For the galaxies in our sample with i < 40 we may have underestimated the BH mass by a factor $0.83 \ ^{4.02} = 2.1$. The gas dispersions predicted by our thin disk models will then be too low by a factor of 2.1 = 1.4. Applying this correction to the predicted gas dispersions for the i < 40 galaxies in e.g., F igure 3 som ewhat reduces the discrepancy between the observed and predicted gas dispersions for these galaxies. Nonetheless, for all four of the galaxies the observed gas dispersions remain well in execss over those predicted by the thin disk models. So our conclusion that radio galaxies have a contribution from non-gravitationalm otions in their central gas dynam ics remains una ected.

7. Conclusions & Discussion

We have analyzed HST/STIS observations of a sample of 27 galaxies. The nuclear velocity dispersion of the gas in a STIS aperture of $0.1^{00} \{0.2^{00} \text{ (i.e., scales of tens of parsecs) generally exceeds the large-scale stellar velocity dispersion of the galaxy. This is qualitatively consistent with the presence of central BHs, but raises the questions whether the excess gas dispersion is of gravitational or non-gravitational origin and whether the implied BH masses are consistent with our current understanding of BH dem ography. To address these issues we have constructed purely gravitational axisym metric dynam icalm odels for the gas, both thin disk models and models with more general axis ratios and velocity anisotropies. This has yielded the follow ing conclusions:$

For the norm algalaxies in the sam ple (i.e., without large-scale radio-jets) the nuclear gas dispersions are adequately reproduced by models that have purely gravitational motion and BHs that follow the M relation. A mong the purely gravitational models we cannot generally discriminate between thin disk models and vertically extended models. The form er might seem preferred theoretically because they represent a longer-term equilibrium con guration for the gas. However, in some cases it is unclear if the observed line pro les are consistent with the double-peaked structure that is generally predicted by thin disk models. The nuclear gas dispersions observed for the radio galaxies generally exceed those predicted by models with only gravitational motions in either a thin disk or a more spheroidal gas distribution. We attribute this to the presence of non-gravitational motions in the gas that are similar to or larger than the gravitational motions. The non-gravitational dispersion is consistent with being either isotropic or perpendicular to the extended gas and dust disks. The non-gravitational motions are presumably driven by the active galactic nucleus (AGN), but we do not nd a relation between the radiative output of the AGN and the non-gravitational dispersion.

G iven the uncertainties about the dynam ical state of the gas, it is not possible to uniquely determ ine the BH m ass for each galaxy from its nuclear gas dispersion. However, for the sam ple as a whole the observed dispersions do not provide evidence for signi cant deviations from the M relation in either active or non-active elliptical galaxies. In no case is the observed nuclear gas dispersion so low that it puts an upper lim it on the BH m ass that is signi cantly below the M relation.

For the normal, i.e., non-radio galaxies, one should note that the success of purely gravitational m odels does not imply that there are no alternative m odels that can t the data. For example, it cannot be ruled out that in reality there is a non-gravitational component to the gas motions, and that the BH m asses in these galaxies are below the M relation. Som e m odels in the literature, such as those published for IC 1459 (Cappellari et al. 2002) fall in this category. Nevertheless, if one is willing to assume a priori that the BH masses of all elliptical galaxies follow the M relation, then one can turn the argum ent around and conclude that norm al elliptical galaxies do not have a very signi cant non-gravitational component in their gasm otions. The absence of excess dispersion in non-radio galaxies is corroborated by the fact that the BH mass estimates for this sample by itself yield a relation in good agreem ent with the M relation (e.g., Figure 3). It is interesting to note in this context that a similarly good correspondence between BH m asses from gas dispersions and from the M relation was found for non-active early-type spiral galaxies by Sarziet al. (2002).

For the low-lum inosity radio galaxies in our sample there is also other evidence, besides the dynam ical evidence presented here, for non- at gas distributions with turbulent motion. The core emission-line lum inosity of these galaxies correlates with the radio and optical core lum inosity which are both most likely due to synchrotron emission from the jet (e.g., Chiaberge et al. 1999; Verdoes K leijn et al. 2002). This correlation could mean that the emission-line lum inosity is driven by jet photo-ionization. It then implies covering factors of 0:3 and hence thick disks (Capetti 2005). A lternatively, the correlation could indicate that the gas is excited by shocks induced by jet-gas interactions.

A lthough it is mostly the radio galaxies that show signi cant excess dispersion over a purely gravitational model, there is one norm algalaxy for which this is the case too: IC 989. It should be noted though that for this particular galaxy the error of 33 km s⁻¹ on the stellar dispersion $_{\rm s}$ = 176km s⁻¹ is larger than typical for the sample. The predicted gas dispersion can be increased by a factor 4 by simply varying $_{\rm s}$ within its 1- con dence range. Also, the predicted gas dispersion could go up by up to a factor 2 if the unknown inclination of the purported gas

disk is closer to edge-on than the default value of 60 that we assumed. So the evidence for non-gravitational gas motions in the norm algalaxy \mathbb{IC} 989 is not strong.

Finally, we note that it is the sample of relatively close to face-on (i < 40) gas disks which revealm ost clearly an excess dispersion compared to a purely gravitationalm odel. Unfortunately, this face-on group only contains radio galaxies. However, a statistically signi cant di erence between the excess dispersion in radio and non-radio galaxies remains when one excludes galaxies with i < 40 gas disks from the analysis. Nevertheless, a good test of the dichotom y found in this paper will be the modeling of gas disks at lower inclinations also in non-radio galaxies. Such data is not available currently.

The evidence for non-gravitational gas motions in radio galaxies makes the gas dispersion unsuited for dynam ical mass estimates in this class of galaxies. It would be interesting to establish more generally whether dynam ical mass estimates from gas velocities, including rotation curves, are robust. This would require comparisons of BH masses from independent indicators (e.g., stellar and gas kinematics) within the same galaxy. Such a comparison has been performed for a radio galaxy (NGC 4335, Verdoes K leijn et al. 2002) and a non-radio galaxy (Cappellari et al. 2002). Unfortunately, in both cases the stellar dynamical evidence is too inconclusive to reach m conclusions. But it does appear in both cases that the BH mass in plied by thin disk models for the gas rotation curves is lower than would otherwise have been expected, either from stellar kinematics or from the M relation. This suggests that the gas might be moving slower than the circular velocity, as would be expected for example if there were asymmetric drift in the gas. This occurs for gas distributions that are dynam ically hotter than a thin disk. More independent BH mass evaluations from gas and other tracers, both for norm al and active galaxies, would be quite valuable to shed more light on these issues.

Support for this work was provided by a grant associated with program GO-9163 from the Space Telescope Science Institute, which is operated by AURA, Inc., under NASA contract NAS5-26555. This paper m ade use of the LEDA database (see http://leda.univ-lyon1.fr). We thank the anonym ous referees for their constructive comments. We thank the rst referee in particular for drawing our attention to the dependence of stellar velocity dispersion on galaxy inclination (see the discussion in Section 6).

This preprint was prepared with the AAS $\mathbb{I}_{E}X$ m acros v52.

Fig. 1. | HST m easured nuclear gas velocity dispersion versus large-scale stellar velocity dispersion for our sam ple galaxies. Open sym bols indicate FR I-type radio galaxies, while solid sym bols indicate galaxies without large-scale radio jets. Most galaxies have nuclear gas dispersions larger than their stellar dispersions (the equality of the two being indicated by the line).

Fig. 2. Observed gas velocity dispersion versus predicted gas velocity dispersion for a thin disk model. We use the BH masses and inclinations inferred from detailed models for the gas rotation velocities available in the literature (see Tables 1 and 2). Open symbols indicate FR I-type radio galaxies, while lled circles indicate galaxies without large-scale radio jets. Circles indicate results from the thin disk models that neglect the contribution of the stellar mass to the gravitational potential. Triangles show the predictions when this sim plication is om itted, for the three galaxies for which we published detailed gas modeling previously. The di erence between the two model approaches is < 10%.

Fig. 3. The observed gas velocity dispersion $_g$ as a function of predicted velocity dispersion for an in nitely thin gas disk in circular rotation around a BH with mass M according to the M relation. Radio galaxies are shown as open symbols and galaxies without large-scale radio jets as

led symbols. Squares indicate galaxies for which the disk inclination is unknown and assumed to be 60. Galaxies with disk inclination i < 40 are indicated by double circles. The typical measurement errors are indicated in the lower right corner. The dashed and solid lines indicate $_{g}$ (model) = $\begin{pmatrix} 1 \\ 1 \\ 2 \\ 1 \\ 2 \end{pmatrix}$ $_{g}$ (obs), respectively, to facilitate comparison to the M relation and its 0.3 dex scatter in BH m ass.

Fig. 4. Ratio of observed and predicted gas dispersions as a function of gas disk inclination. The predicted dispersion is assumed to be caused by the circular rotation in a thin disk around a BH according to the M relation. The error bars take into account the 0.3 dex intrinsic scatter in the M relation, and typical errors due to aperture di erences and dispersion measurement errors. The four arrows indicate where points will move if disk inclinations were underestim ated within the measurement errors for close to face-on disks. Radio galaxies (open symbols) have a system atically larger dispersion ratio than non-radio galaxies (led symbols). The squares indicate galaxies for which the dust does not provide a constraint on the gas disk inclination (placed at

ducial inclination of 60). If the assumed disk inclinations are incorrect, and the observed gas is actually edge-on in all galaxies, then we would have expected the ratios to lie along the solid line $\sin^{-1} i$. Since m any points lie above this line, inclination errors cannot be the (sole) explanation of the observed trend.

Fig. 5. The ratio of the velocity dispersion for a collision less spheroid divided by that of a thin disk with identical projected surface density prole, as a function of apparent axis ratio. The small dots indicate spheroid models with varying intrinsic axis ratios, powerlaw density slopes and velocity dispersion anisotropies. The ratios of observed velocity dispersions and dispersion predicted by thin disk models from Figure 4 are overplotted. Symbols are as in Fig. 4.

Fig. 6. Top: The ratio between the observed dispersion and the maximum dispersion expected from spheroids or thin disks for radio galaxies with determ ined inclinations. The ratio is system atically above 1. M iddle: The ratio of non-gravitational dispersion $_{iso}$ and gravitational dispersion $_{grav}$ for a two component gas model which matches the observed dispersion. The model has a circular thin gas disk which causes $_{grav}$ measured in the plane of the disk and a non-gravitational component with an isotropic gas dispersion $_{iso}$. B ottom : Sim ilar to middle plot, but now the non-gravitational dispersion component is assumed to be perpendicular to the gas disk.

Fig. 7. $|R_{od}$ versus total radio power at 1.4G H z for radio galaxies (open symbols) and non-radio galaxies (led symbols). A s show n before, radio galaxies have system atically larger R_{disk} . How ever, no system atic trend is seen between the radiative power of the AGN at radio wavelengths and the excess dispersion within the radio galaxy sample.

Fig. 8. Top: angular radius inside which half of the total gas emission is contained versus distance for radio galaxies (open circles) and non-radio galaxies (led circles). The half light radius of the PSF for these observations is 0.05^{00} . Bottom : same as top panel, but now the half light radius is expressed in parsec.

Fig. 9. Stellar velocity dispersion as a function of host magnitude for the sample galaxies. Galaxies with dust disks with i < 40 are indicated by a double circle.
