

Generic morphologies of viscoelastic dewetting fronts

A simple model is put forward which accounts for the occurrence of certain generic dewetting morphologies in thin liquid coatings. It demonstrates that by taking into account the elastic properties of the coating, a morphological phase diagram may be derived which describes the observed structures of dewetting fronts. It is demonstrated that dewetting morphologies may also serve to determine nanoscale rheological properties of liquids.

When a thin liquid film beads on a solid substrate, it is eventually transformed into an ensemble of individual liquid droplets, the arrangement of which may vary strongly according to the basic mechanisms involved in the dewetting process [1,7]. In by far most cases, dewetting is initiated by heterogeneous nucleation of individual holes in the initial film, thus forming contact lines between the film surface and the substrate. The surface forces acting upon these contact lines give rise to moving dewetting fronts, the motion, shape, and interplay of which largely determine the final dewetting morphology.

It would be very desirable to have a theory describing the dynamics of these fronts precisely enough for extracting information on the dewetting mechanisms from the characteristics of their shape and the final droplet structure. However, the task of setting up such a theory has proved untractable so far. Solving the Navier-Stokes equation with the moving contact line as a boundary condition is particularly complicated and entails ad hoc assumptions on the dynamics at the contact line [8,10]. Furthermore, it has meanwhile become clear that viscoelastic effects, which are not described by the Navier-Stokes equation, may be decisive for the evolving morphology in both advancing and receding fronts [4,11,14]. In particular, it has recently been shown [13,14] that elastic dewetting fronts may strongly differ, as to their shape and dynamics, from Newtonian ones [15], and it has been pointed out that these findings are not accounted for by theory so far [13]. Consequently, what is needed is a handy theoretical model, which is just as detailed as necessary to describe the main physics involved in the dewetting dynamics of viscoelastic films. It is the purpose of this paper to propose such a model.

Let us first recall the main features to be explained, by summarizing the generic front morphologies observed so far. Fig. 1 shows dewetting fronts in liquid polystyrene films beading on silicon substrates (the fronts move from

left to right). The profiles are obtained by scanning force microscopy from the rims of circular dry patches nucleated in the films [16,18]. Most commonly, one observes profiles as those shown in Fig. 1a, with a simple decay from the crest into the undisturbed film to the right. However, when the molecular weight of the polymer is small enough [14], the shape may be qualitatively different. This is shown in Fig. 1b, which has been obtained with polystyrene films with a molecular weight of only 2 kg/mol. A ditch is clearly visible in front of the crest, and even another small elevation to the right of the ditch is present as well, such that the front appears as a damped oscillation. The only difference between the film materials used for Fig. 1a and 1b is their molecular weight, and thus their viscoelastic properties. If the film is not too thick, the ditch may reach the substrate and pinch off the crest from the film, forming a new contact line. This happens repeatedly, such that a series of isolated crests forms in a cascade of pinch-off events, as shown in Fig. 1c.

We shall now create a suitable mathematical description of these findings. An incompressible viscoelastic fluid may be described by the force balance [19,21]

$$j = \eta p - E \epsilon \quad (1)$$

where η is the viscosity, j is the material current in the film, p is the pressure, E is Young's modulus, and ϵ is a local displacement field describing the strain [21,22]. In the present treatment, we will adopt the lubrication approximation [23], thereby neglecting the normal (z -) components of the current and the pressure gradient, and consider quantities averaged over the film thickness, h . We then can rewrite eq. (1) as $J(x) = C \partial_x (p - E \epsilon)$, where J is the total current in the film, and C is a numerical factor which characterizes the flow profile. The latter depends, e.g., on the friction of the film at the substrate, and it is clear that in the case of full slippage, the coupling of the flow to the strain will not be the same as in the absence of slip. These effects are difficult to treat explicitly, and thus will be absorbed here into C . Similarly, C depends upon the viscosity of the film, η , and its friction coefficient at the substrate surface, β . If the latter is infinite (Poiseuille flow with no slip at the substrate), we have $C = h^3/3$, while for $\beta \rightarrow 0$ (plug flow), $C = h^2/2$ [15,23].

Since the derivative of the displacement is the strain, $\epsilon(x;t) = \partial_x u$, and excess pressure in the film comes about from the curvature of its surface, we have

$$J(x;t) = C \partial_x f \partial_{xx} u(x;t) + E \partial_{xx} u(x;t) g \quad (2)$$

where γ is the surface tension, and $(x;t)$ is the vertical displacement of the ℓ_m surface. We explicitly neglect long range wetting forces acting through the ℓ_m , such as van der Waals forces. In sufficiently thick ℓ_m s, which dewet by nucleation [17,24] (such as assumed above), these do not play a significant role.

Since the strain in the ℓ_m may decay by internal relaxations of the material according to $\partial_t \epsilon = -\epsilon/\tau_0$, its coupling to the material current can be written as [21,22]

$$(\partial_t + 1/\tau_0) \epsilon = \partial_x J = h \quad (3)$$

where we have neglected the nonlinear convective term $J \partial_x \epsilon$. This restricts our discussion to small excursions ϵ , but enables a linear treatment. By combination of the above equations with the continuity equation, $\partial_t \epsilon + \partial_x J = 0$, it is easy to obtain the equation of motion for ϵ and J . A precondition for elasticity to play a significant role is that $1/\tau_0 < \omega$, in which case the dispersion relation reads

$$\omega = \omega_0 + C q^2 \frac{E}{h} + \frac{1}{2} q^4 \quad (4)$$

where q is the wave number of the perturbation.

In order to determine the shape of the moving dewetting front, we now look for travelling-wave solutions of the form $(x;t) = (x - vt)$, where v is the velocity of the dewetting front. We remain in Fourier space, i.e., we decompose the front profile into modes $q / \exp(iqx - \omega t)$. Writing $Q = i\omega h$, it follows that $\omega = Q/v = h$, and from eq. (4) we then get

$$Q^4 - \frac{E h}{C} Q^2 - \frac{v h^3}{C} Q + \frac{1}{2} h^4 = 0 \quad (5)$$

As it will become clear below, the term $1/2 h^4 = C$ is rather small. If we neglect it for the moment, we get the cubic equation

$$Q^3 - E' Q - \frac{1}{2} v = 0 \quad (6)$$

where we have introduced the dimensionless quantities $v = \frac{v h^3}{C}$ and $E' = \frac{E h}{C}$. This can be easily solved, and the solutions of the quartic equation (5) turn out to deviate significantly from those of the cubic equation only for parameters which are not relevant in most experimental situations. We will thus primarily discuss eq. (6), and refer to eq. (5) only occasionally, where appropriate.

If viscoelastic effects are absent, i.e. $E = 0$, we have $Q = \frac{1}{2} v$. We are interested only in modes with $\omega < 0$ [25], which are $Q = \frac{1}{2} v (1 \pm i\sqrt{3})$. The shape of the real surface of the leading front is thus $\epsilon / e^{\frac{1}{2} \sqrt{3} x} \cos(\frac{1}{2} \sqrt{3} x)$ [14,26], which clearly exhibits not only a ditch, but a damped oscillation. For Newtonian liquids, it can be seen from numerical solutions of the Navier Stokes equation for the moving front problem that this result does

not depend on the friction of the ℓ_m at the substrate [11,12]. A profile like that is shown in fig. 1b, and it is obtained only for small molecular weight indeed, where elastic effects are particularly small. The real and imaginary part of Q can be determined from the profile, and in the case of the one displayed in fig. 1b, it turns out that they are not precisely as expected for a Newtonian fluid [14]. Since the complex roots of eq. (6) satisfy the relation

$$3 < (Q)^2 = (Q)^2 = E' \quad (7)$$

the elasticity of the ℓ_m can be inferred from the measurements, and we get $E = 8.7$ kPa. We would like to point out that this is a non-invasive method of determining rheological properties of liquids on a sub-micron scale.

As the height of the crest, H , increases while more material is collected in the front, the amplitude of the oscillation increases, and so does the depth of the ditch [14]. When the latter reaches the substrate, the crest is pinched off and a cascade is formed as shown in fig. 1c. However, this works only as long as the width, W , of the crest is less than half the wavelength of the damped oscillation. As H increases, so does W [17,23], with the ratio $H = W = G(\theta)$ being only a function of the dynamic contact angle at the substrate, θ [17]. For a cylindrical rim [23], we have simply $G(\theta) = (1 - \cos \theta) = 2 \sin^2 \frac{\theta}{2}$. For more asymmetric shapes, the form of G is different, but similar as to the overall behavior and the order of magnitude. If W is larger than $W_c = \lambda/2 = \lambda/2 = G(\theta)$, the depth of the ditch is rather determined by the contact angle of the rim at the leading edge. Consequently, it will reach a natural maximal depth [14], and a dry spot forms only if this depth exceeds the ℓ_m thickness. The condition for a cascading front to form is readily seen to be

$$G(\theta) > \frac{1}{2} \exp \left(\frac{G(\theta)}{G(\theta)} \right) \quad (8)$$

As the ℓ_m thickness is decreased, so is the right hand side of eq. (8) (h cancels out in the exponential), such that a cascade is expected at sufficiently small h . Eq. (8) can be used to determine the boundary line for the appearance of cascade structures in the $(v; E')$ -plane. In fig. 2a, this is indicated by the lower curve for $G = 1$. For different values of G , the maximum of the boundary line, indicated by the dot in the figure, is quite accurately described by $E' = 0.060 G^2$. For very thin ℓ_m s, where van der Waals forces play a role, the cascade region will slightly extend or shrink, depending on the sign of the Hamaker constant.

Let us now turn to the influence of stronger elastic effects. It is interesting to investigate at which system parameters the damped oscillation, as shown in fig. 1b, vanishes. These are given by the zero of the discriminant of the cubic equation (6), which is

$$D = \frac{\nu}{2} \frac{E^*}{3} \quad (9)$$

The critical modulus above which there is no oscillation is thus given by $E^* = 3 \frac{\nu}{2} \frac{1}{3}$. This may be viewed as an 'other morphological phase boundary' in the (E^*, ν) -plane, and is shown in Fig. 2a as the upper solid curve. The exact boundary, according to eq. (5), deviates noticeably only for very small values of E^* and ν . To quantify this deviation, it is useful to introduce the dimensionless parameter $\Phi = \nu_0 h = \nu$, which represents the importance of intrinsic relaxation in the material with respect to the shear flow exerted by the dewetting process itself. In Fig. 2b, the 'exact' phase boundary, which was determined by solving eq. (5) graphically, is shown as the solid curve, along with the approximation obtained from the cubic equation (dashed line). For $\Phi \rightarrow 0$, the solid curve approaches the dashed line asymptotically. The diagram presented in Fig. 2a, which corresponds to $\Phi = 0$, shall thus be considered quite reliable within the range displayed if $\Phi < 0.1$ (in the experiments in ref. [13], $\Phi \approx 10^{-5}$).

The two complex conjugate roots giving rise to the oscillations for $D > 0$ merge into a degenerate real root at a critical elastic modulus ($D = 0$). As the latter increases further, they bifurcate again into two real roots, Q_{long} and Q_{short} . In fact, 'elastic' fronts can be well fitted by a superposition of two exponentials, as shown in Fig. 1a by the dotted curves. The model predicts the ratio $Q_{\text{short}} = Q_{\text{long}}$ to increase with E^* , and thus the front to become more and more asymmetric, in accordance with observation [4,13,14]. We can again determine E^* from the front profile via the relation

$$\frac{Q_{\text{long}}}{Q_{\text{short}}} = \frac{\sin f_6 - \frac{1}{3} \arccos B}{\sin f_6 + \frac{1}{3} \arccos B} \quad (10)$$

with $B = \frac{3}{2} \frac{\nu}{E^*} \frac{1}{3} \frac{1}{3} \frac{1}{3}$, once the constant C is known for the system.

The long range shape of the front is determined by the smaller root, Q_{long} , which asymptotically approaches the simple law $Q = \nu E^*$. Thus the width of an elastic front should remain constant during dewetting, in agreement with recent observations [13], but in contrast to quasi-Newtonian fronts [15,23]. Since our model predicts Q_{short} to scale as E^* for sufficiently large E^* , we have $Q_{\text{long}} / Q_{\text{short}}^2$ if all other parameters in the system are kept constant. In fact, for the two curves shown in Fig. 1a, the ratio of the Q_{long} is 1:40 \pm 0.07, while the ratio of the Q_{short}^2 is 1:34 \pm 0.13. This is clear agreement.

We thus have put forward a tractable model which describes the generic morphologies of liquid dewetting fronts observed so far. It correctly accounts for the impact of the fluid properties upon their occurrence and structure. It is thereby capable of extracting information on the sub-micron scale rheological properties of the liquid from the observed profiles. This may be rendered

quantitative by determining the numerical constant, which we leave to further work.

The authors are indebted to Klaus Mecke and Ralf Blossey for many fruitful discussions. We also thank Gunter Reiter for stimulating remarks. Funding from the Deutsche Forschungsgemeinschaft within the Priority Program 'Wetting and Structure Formation at Interfaces' is gratefully acknowledged.

FIG. 1. Dewetting morphologies observed in various liquid polystyrene films beading on a silicon substrate. The height has been normalized with respect to the film thickness. a) Profiles of the rims of holes nucleated in 40 nm thick films. The steep profile was obtained with a molecular weight of $M_w = 101$ k, the latter profile with $M_w = 600$ k. Each profile is superimposed with a double exponential fit as a dotted line, the agreement is almost perfect (see text). b) Profile obtained with $M_w = 2$ k. c) Same as b), but with smaller film thickness.

FIG. 2. a) Morphological phase diagram for viscoelastic dewetting fronts in the $(\tilde{E}; \tilde{\nu})$ -plane, according to eq. (6). b) Deviation of the phase boundary according to eq. (5) (solid curve) from the approximation given by eq. (6) (dashed line).
