#### Abstract

A recently proposed convolution technique for the calculation of localdensities of states (LD O Ss) is described $m$ ore thoroughly and new results of its application are presented. For separable system $s$ the exposed $m$ ethod allow $s$ to construct the LDOS for a higher dim ensionality out of low er dim ensional parts. Some practical and theoretical aspects of this approach are also discussed.

## 1 Introduction

Recently we proposed and dem onstrated a new convolution technique for the calculation of the localdensity of states $[1,2]$. The idea of this novelapproach is intuitively accessible, so we had not yet exposed its $m$ athem atical description. The analytic form ulation $\circ$ ers the advantage of a $m$ ore com prehensive view about the interplay of param eters in the utilized $m$ odels, which could be bene cial with view to further developm ents. Exact analytic results being rather scarce in this area [3-6], the calculations of the LD OS and other characteristics rely on num erical schem es but usually they becom e a cum bersom e task even for som e of the $m$ ost sim ple system $s$. In consequence, a wealth of altematives has
been produced and am ong them the ones exploting tight-binding (TB) m odels appear as particularily useful [7-9]. The TB approxim ation also provides a convenient fram ew ork for the present work. T he approach considered here proposes to utilize in a constructive $m$ anner the already know LDOSs in analytic or num eric form, no $m$ atter how they have been arrived at.

## 2 M odel and M ethod

$W$ ithin the tight-binding $m$ gdelthe $H$ am iltonian ofa sim ple $D$-dim ensionalcrys tal is written as $H=+2$ i $i \cos \left(k_{x_{i}} d_{i}\right), i=1: D$. C onsidered from a statistician's point of view, the distribution of the values generated by a form such as H is a 'com position' or 'convolution' [10] of the distributions of its additive parts which correspond to the independent variables. Thus, the eigenvalues of the system are indeed obtained by a com bination of eigenvalues corresponding to its com ponents. A ccordingly, separating the system into a one-dim ensional part and a D-1 dim ensional subsystem, the LDOS of a the whole system can be obtained from the subsystem $s$ w ith $s m$ aller dim ensions through the recurrence:
$(\mathrm{D})=\left(\begin{array}{ll}\mathrm{D} & 1\end{array}\right) \quad(1)$
where ${ }^{(0)}=$ and the sign denotes the convolution operation. T he idea of this approach is presented graphically in F ig.1. For a better view all the curves in this plot have been scaled to a sam e maxim um height, instead of keeping the sam e (unit) area. If the singularities of the one-dim ensional curve are well pronounced, they are reproduced in subsequent calculations, as it can be seen on this gure.

In order to have a m ore substantial derivation we proceed in the opposite direction, starting with $\mathrm{D}=1$. In this case the H am iltonian is $\mathrm{H}=\quad+$ $2 \cos \left(k_{x}\right)$.T he distance $d$ is assum ed to be $d=1$ and the energy is expressed everyw here below through the dim ensionless variable $\mathrm{E}=(\quad)=2$.

From the $m$ eaning of LD OS one can write directly $d k \quad(E): d E$ i.e.
$\mathrm{dk}=\mathrm{dE}$. For oscillators, as it has been noted $\quad 1=\dot{j} \dot{j} \mathrm{v}=\mathrm{dE}=\mathrm{dk}$ being the group velocity or m ore generally [11] v $=\operatorname{grad}_{k}(E)$. So for this $H$ am iltonian $\mathrm{k}_{\mathrm{x}}=\operatorname{arcos}(E)$ and thus
${ }^{(1)}=\mathrm{P} \frac{1}{\left(1 \mathrm{E}^{2}\right)}$,
the coe cient $1=$ being written in order to scale the overall density to a unit, assum ing it is equal to zero outside the energy interval $(-1,1)$. In two dim ensions $H=+2\left(\cos \left(k_{\mathrm{x}}\right)+\cos \left(\mathrm{k}_{\mathrm{y}}\right)\right)$ and in the sam e way we obtain for the partialLD O S

$$
y=p \frac{1}{1\left(E \cos \left(k_{y}\right)\right)^{2}} .
$$

Integrating for all values of $k_{y}$ and substituting $k_{y} w$ ith $\operatorname{aroos}(u)$, after inverting the integration lim its, the LDOS is
(2) $=\frac{1}{2} R_{1} p \frac{1}{1(E \quad u)^{2}} p \overline{u^{2}} \mathrm{du}$.
$T$ he obtained form ula is the canonical expression for a convolution,

$$
f(x)=R_{1} g(x \quad) h() d,
$$

for which the usual notation $f=g \quad h$ has been adopted. In our particular case $g$ and $h$ are indeed the sam efunction and thus we have a self-convolution, which can be of special interest), but this does not need to be so as our exam ples in the next section dem onstrate. T he sam e consideration is applicable to higher dim ${ }_{R} R_{R}$ sionalities as the $m$ ultiple integrations are consecutive convolutions e.g.

would lefen ore generally
$f(x)=g((x \quad) \quad h() l() d d$,
or $f=g \quad h \quad l$ for some functions $f ; g ; h$ and $l$ representing LD OSs. The advantages of this approach appear to be fairly obvious: the results for $m$ ore sim ple system $s$ are utilized to obtain know ledge about m ore com plicated ones. $M$ ost often such results are available in $\mathbf{p}^{n u m}$ eric form and then the convolution is im plem ented sim ply as the sum $f_{k}={ }_{i} g_{k} i_{i}$. H ow ever a m ore sophisticated procedure $m$ ight be needed in order to evaluate precisely the integral which represents it. In our partiqplar case it m ay be noted that the quadratures for expressions containing $1=\overline{\left(1 \quad x^{2}\right)}$ can be e ectively sim pli ed [12]. A lso, as it is known, a convolution can be expressed in Fourier space by a simple multiplication of the transform s and here we have ${ }^{(D)}$ ) FT ( $j J_{\circ}^{D}$ ) . A ny way, the com putational advantages of this $m$ ethod can be considerable as it was already pointed [1].

## 3 Results and D iscussion

A s exam ples of application we shall consider brie $y$ tw o cases of sem i-in nite structures and also o er a com ment on thee ect ofan electric eld in the present context.

For the sim plem odel consisting of tw o in nite wires in interaction or, which is the sam e , an in nite chain of dim ers, the convolution $m$ ethod readily $o$ ens a solution. The LD O S for a dim er is given [13] by the form ula:
$=\frac{1}{} \operatorname{Im} \operatorname{ag}\left(\frac{\mathrm{~g}}{\left(1 \frac{\left.\mathrm{~g}^{2} \mathrm{t}^{2}\right)}{}\right),}\right.$
$w h e r e g(E)=1=(E+i)$ is the $G$ reen function for an isolated atom and $t$ is the interaction betw een atom $s$ (in the dim er). The explicit expression for the LDOS is a sum of two Lorentzians centered at $t$ and whose width is vanishingly sm all. In the lim it, as they tend to delta functions, the convolution produces a sum of two one-dim ensionalLDOSs centered now at $t$ : $(E)=\frac{1}{2}\left({ }^{(1)}(E \quad t)+{ }^{(1)}(E+t)\right)$.
$F$ ig 2 presents the result for this $m$ ost sim ple case. M odifying the value of the interaction $t$ would just change the distance betw een the delta peaks and this willbe re ected in the overlap of the one-dim ensionalLD OS, whose width is govemed by . A n algebraic treatm ent for a nite variant of this structure is found in Ref.6. M ore com plicated cases are accessible when the poles of
the $G$ reen fiunction are know $n$. Indeed, if one chooses to consider the LD O Ss as consisting of Lorentzian (or G aussian) peaks whose centers are distributed follow ing som e law , e.g. a cosine for one dim ension, then the convolution w ould a ect only the distribution, as it produces out of tw o such peaks a new one w ith a larger fullw idth at halfm ax.

A nother case of a sem i-in nite structure is the model of a slab which is in nite in along two axes and restricted to only one side of the third. In this case the LD OS corresponding to an in nite plane should be convoluted w th the LDOSs for atom $s$ in a sem i-in nite chain, which are di erent according to their distance from the origin [13]. This has been ilhustrated in Fig. 3 which in fact reproduces results presented by $H$ aydock and $K$ elly and who in their tum were assessing the possibilities of their own approach by repeating a plot originally show $n$ in $K$ alkstein [14]. T he last curve in the plot is essentially a replication of the low er row of curves in $F$ ig. 1 as for atom $s$ far from the beginning of the chain the LDOS is the same as in an in nite structure. H ow ever one $m$ ight presum $e$ that here we have gained som e insight into the constitution of these well know $n$ results.

A dopting this view, we could reconsider the e ect of a constant electric eld on the LDOS [15]. Here the analytic result is known for the one-dim ensional case [5] and it has to be convoluted $w$ ith its an appropriate counterpart in order to obtain the results of interest [1]. As it was pointed, a convolution can be expressed in Fourier space by a $m$ ultiplication, and this form $m$ akes it easier to account for the e ect of an electric eld: the Fourier Transform of $J_{0}(2 \sin (!)=F)$, where $F$ is the eld strength along the axis, $m$ atches [16] the result for an in nite chain obtained by Davison et al. The FT of the LDOS, being represented by a product ofsuch factors corresponding each to an axis, for higher eld strength along any one of them, tums into a constant ( $\mathrm{L}_{\mathrm{O}}(0)=1$ ), so its original is now a delta fiunction and the dim ensionality of the system is low ered. The physical aspect of this phenom enon has been considered in the work already m entioned as Ref. 15 .

The lim itations for this way of proceeding are fairly evident as it relies on the additivness of the H am iltonians. H ow ever som e insight in the production of the LDOS has been gained. For instance, a ${ }^{(2)}$ curve now can be seen as (the passage to the lim it for) a weighted sum of ' $U$ ' shapes centered at di erent energies. If second neighbours are to be inchuded in the tight-binding H am iltonian, it ceases to be additively separable but it still can be factorized, now as a product, and then the sum $m$ ation would include not just w eighted and displaced one-dim ensional ' $U$ ' shapes but ones with a di erent spread. This suggests that our constructive approach could perhaps o er further possibilities for the calculation of $m$ ore com plicated cases.

## C onclusion

The proposed technique allows to utilize e ectively already obtained results and to extend them further. It is able to generate new ones and in $m$ any instances otherw ise di cult to obtain results becam e easily accessible. H ow ever the $m$ ethod relies on the separability of the $H$ am iltonian, which severely lim its its scope. The analytic form ulation of the $m$ ethod suggests a novelview even if the com plexity of the calculations $m$ ost often de es their com pletion. T he convolutional form has a rather intuitive $m$ eaning, which $m$ ight be $m$ ore intelligible than the abstract elliptic integrals expressing the sam e result.
