# Phase D iagram of the quadrum erized Shastry-Sutherland M odel 

A ndreas Lauchli, Stefan W essel, and M anfred Sigrist Institut fur T heoretische P hysik, ETH H onggerberg, C H -8093 Zurich, Sw itzerland (A pril 14, 2024)

#### Abstract

W e determ ine the phase diagram of a generalized Shastry-Sutherland $m$ odel, using a com bination of dim er- and quadrum erłboson $m$ ethods and num erical exact diagonalization techniques. A long special lines in the param eter space the $m$ odel reduces to the standard Shastry-Sutherland $m$ odel, the $1 / 5$-th depleted square lattice and the tw o-dim ensionalplaquette square lattice $m$ odel. W e study the evolution of the ordered phases found in the latter two unfrustrated models under the e ect of frustration. Furtherm ore we present new exact diagonalization results for the Shastry-Sutherland $m$ odel on clusters w ith up to 32 sites, supporting the existence of an interm ediate gapped valence bond crystal phase w ith plaquette long-ranged order.

There has been considerable interest in recent years in the study of low-dim ensional quantum spin system $s$, both experim entally and theoretically. Special attention has been devoted to two-dim ensional antiferrom agnetic system S , where quantum uctuations and frustration allow for various exotic quantum phases to com pete with quasi-classical long-range $m$ agnetic order. [ī1]

A lready in the unfrustrated regim e such spin liquid phases occur in certain regions of the param eter space, a prom inent exam ple being the spin $-1 / 2 \mathrm{H}$ eisenberg m odel on the $1 / 5$-th depleted square lattice. $\overline{\ln }$ In In is $m$ odel two distinct spin liquid phases, well described by resonating valence bond (RVB) -like states, are found along with an interm ediate long-ranged antiferrom agnetically
 points separating these phases are known to rather high precision. []

W hen considering frustrated system s , ground state properties are less w ellestablished. A prom inent exam ple of recent interest, due to its relevance for the spin gap sys-
 (SSM ). [7] In this $m$ odel the nearest-neighbor square lattice antiferrom agnet is frustrated by additionaldiagonal interactions, arranged in a staggered pattem on alternate squares. This $m$ odel retains long-range $N$ eel-order for $s m$ all diagonal coupling. Furtherm ore, it becom es an exact dim er valence bond solid (VBS) w ith singlets form ing on the diagonalbonds for sm allaxialcoupling. C onœming the existenœ and nature of interm ediate phases, despite num erous investigations, [8-12], a de nite picture has not yet em erged.

## I. THEMODEL

In this paper, we present exact diagonalization studies on the SSM that indicate the occurrence of a valence bond crystal (VBC) in the interm ediate regim e, with plaquette long-range order. Furtherm ore, we are able to link this phase to a consistent phase diagram of an extension
of the SSM. Therefore, we introduce the quadrum erized SSM, de ned on the square lattice by the follow ing spin1/2 H eisenberg H am iltonian

$$
H=K_{h i ; j i_{2}}^{X} S_{i} \quad S+J_{h_{i ; j i_{2} 0}^{X}}^{X} \quad S_{i} \quad S+J_{\text {hhi;jii }}^{J_{i}} \quad S_{i} \quad S: \quad \text { (1) }
$$

$H$ ere $K$ and $J$ are the tw o inequivalent nearest neighbour exchange couplings, whereas $J^{0}$ denotes the next nearest neighbour altemating dim er coupling. T he various couplings are displayed in F ig. 1.

FIG.1. The quadrum erized Shastry-Sutherland lattice. A spin-1/2 degree of freedom is located on each vertex. T he various couplings, represented by di erent line styles, are denoted $K$ (solid), $J$ (dashed), and $J^{0}$ (dotted). The lattice is self-dual under the exchange ( $J$ \$ K ). A rrow s illustrate the ordered phase found for $J=0$ in the region $J^{0} \quad \mathrm{~K}$.
$N$ ote, that the lattice is self-dual under the exchange ( $J \$ K$ ), hence only the case $J \quad K$ willbe considered. Furthem ore, the standard Shastry-Sutherland m odel is recovered along $J=K$, and has a larger space group sym $m$ etry. O ther lines ofenhanced sym $m$ etry correspond
to the $1 / 5$-th depleted square lattioe ( $J=0$ ), and the plaquette square lattice ( $J^{0}=0$ ), respectively.

The paper is organized as follows: In the next section we present the phase diagram of the quadrum erized SSM as obtained from boson operatorm ean- eld theory. $T$ hen in the third section we use exact num erical diagonalization to study the e ects of frustration in the $m$ odel and relate the num erical results to the $m$ ean- eld phase diagram. W e concentrate on the standard SSM in the fourth chapter and provide evidence for a VBC interm ediate phase. A sum $m$ ary and conclusions are given in the nal section.

## II. BOSON OPERATORAPPROACH

W e rst review the num erical results obtained along the unfrustrated lines in the param eter space of the H am iltonian (1). For the $1 / 5$-th depleted square lattice ( $J=0$ ) there exists a plaquette RVB-like phase (PRVB) at sm all $J^{0}=K<0: 94$, and a dim er RVB-like phase (DRVB) at large $J^{0}=K>1: 67$, $w$ th an interm ediate long-range ordered antiferrom agnetic phase. $\left[\begin{array}{ll}{[-1+1}\end{array}\right] T$ he classical con guration corresponding to this order is depicted by the arrow s in F ig. 1.

The plaquette square lattioe $\left(J^{0}=0\right)$ is unfrustrated as well. U sing stochastic series expansion quantum $M$ onte C arlo sim ulations a quantum critical point is found at ( $J=K$ ) $c \quad 0: 55$, separating a PRVB spin liquid for $J=K<$ ( $J=K$ ) $C$ from a gapless $N$ el-ordered phase. [13] Th his value agrees well w th results from perturbation expansions. [14, ${ }^{\prime}$
W hile quantum $M$ onte Carlo proves powerfiul for studying the unfrustrated lim its of the H am iltonian (1), due to the sign problem other $m$ ethods are needed, once frustration is present. In order to study possible instabilities of the spin liquid phases, we use standard boson operatorm ean- eld theory, which is known to work on a qualitative level even for large frustration. O ur analytical results will also be substantiated by the num erical approach of the follow ing sections.

## A.D im er-boson approach

C onsider rst the DRVB regim e $J^{0} \quad J ; K$ where the dim er-boson technique can be applied. [15문 In this representation, the spin $-1 / 2$ degrees of freedom on each $\mathrm{J}^{0}$ dim er are expressed by bosonic bond operators,

$$
\begin{aligned}
& \text { jisi }=s^{y} j 0 i=j 0 ; 0 i ; \\
& J_{+} i=t_{+}^{y} j 0 i=j ; 1 i ; \\
& \mathrm{t}_{0} i=\mathrm{t}_{0}^{\mathrm{y}}-\mathrm{j} 0 \mathrm{i}=1 ; 1 ; 0 i ; \\
& \text { J } i=t^{y} j 0 i=1 ;+1 i ;
\end{aligned}
$$

where the $j_{i} ; S^{z}{ }_{i}$ denote the states on a given dimer. From the action of the spin operators $S_{i}, i=1 ; 2$ (denoting the two sites of a dim er) on these states the representation of the spin operators can be deduced

$$
\begin{array}{ll}
S_{i}^{z}=\frac{1}{2} t_{+}^{y} t_{+} \quad t^{y} t & \frac{(1)^{i}}{2} t_{0}^{y} s+s^{y} t_{0} ; \\
S_{i}=\frac{1}{2} t^{y} t_{0}+t_{0}^{y} t & \frac{(1)^{2}}{2} t^{y} s \quad s t: \tag{3}
\end{array}
$$

The spin com $m$ utation relations for $S_{i}, i=1 ; 2$ are obtained when the bond operators obey bosonic statistics. Furtherm ore, the num ber of physical states available on each dim er speci es a hard-core constraint for the bosons on each dimer ,

$$
\begin{equation*}
s^{y} s+t_{;+}^{y} t ;++t_{; 0}^{y} t ; 0+t^{y} ; t ;=1: \tag{4}
\end{equation*}
$$

Taking the interdim er couplings $J$ and $K$ into account and using Eq. $(\overline{3})$, , the H am iltonian (1) is m apped onto an equivalent bosonic $H$ am iltonian, $H^{D}=H{ }_{0}^{D}+H_{I}^{D}$, containing quadratic, diagonal term s
$H_{0}^{D}=J^{0} \quad \frac{3}{4} S^{y} s+\frac{1}{4} t^{y}+t ;+t^{y} ; 0 t ; 0+t^{y} ; t ; \quad ;$
and quartic term $s, H_{I}^{D}$, describing the interdim er scattering. $T$ he square lattice ofdim ers, $w$ ith tw o dim ers per unit cell, is found to reduce to a square lattioe w ith a single site per unit cell in the bosonic representation. H ere, we rst im agine rotating half of the $J^{0}$-dim ers clockw ise, so that alldim ers align along the ( $1,-1$ )-direction (cf. Fig. 1). Then we take the centers of the dim ers as the sites and use a coordinate system where $x_{D}$ is along the original ( $1,-1$ )-direction and $Y_{D}$ along ( 1,1 ). To proceed, we need to im plem ent the constraint $(\overline{4})$ by m eans of a H olsteinPrim ako representation, [1]
and then decouple the quartic $H_{I}^{D}$ via a linear approxi$m$ ation, sim ilar to linear spin w ave theory. T he resulting totalquadratic H am iltonian, $\mathrm{H}^{\mathrm{D}}$, is then diagonalized in m om entum space using a generalized B ogoliubov transform ation. [1] $T$ his approach is expected to work well inside the DRVB phase. A threefold degenerate spectrum of triplet excitations is obtained, consistent $w$ ith unbroken SU (2) sym m etry,

$$
\begin{equation*}
\left.\left.!\left(k_{D}\right)=q \overline{J^{0}\left[J^{0}+(K\right.} \quad J\right)\left(\operatorname{cosk}_{x} \quad \operatorname{cosk}_{y}\right)\right]: ~ \tag{5}
\end{equation*}
$$

Here, the wave vector $k_{D}=\left(k_{x} ; k_{y}\right)_{D}$ is de ned with respect to the dim er coordinate system ( $x_{D} ; y_{D}$ ). The phase boundaries of the DRVB phase are obtained from the instabilities of the triplet excitation spectrum, i.e. by a vanishing spin gap at $k_{D}=(; 0)_{D}$, signaling the condensation of the corresponding bosons at this wave vector. [1]-] M apping back onto the original square lattice,
the corresponding $m$ agnetic order is obtained, characterizing the phase beyond the instability line $2\left(\begin{array}{ll}\mathrm{K} & \mathrm{J})\end{array} \mathcal{f}\right.$. In fact, this $m$ agnetic order corresponds to the long-range order found for the $1 / 5$ th depleted square lattioe, c.f. Fig. 1.

## B. Q uadrum er-boson approach

W hen the param eters in the H am iltonian of Eq. (1) are close to another $\lim$ iting case, $J ; \mathrm{J}^{0} \mathrm{~K}$, a sim ilar approach, the quadrum er-boson technique, can be applied. [1d] T he Ham iltonian of a single quadrum er, $\left.H=\begin{array}{lllll}K & S_{1} & S+S_{2} & S+S_{3} & S+S_{4} \\ S\end{array}\right]$, can be expressed in term s of the total spin, $S=S_{1}+S_{2}+S_{3}+S_{4}$, and the total subspin on each diagonal, $S_{A}=S_{1}+$ $S_{3}$, and $S_{B}=S_{2}+S_{4}$. The spectrum is given by $E\left(J_{S} ; S^{z} ; S_{A} ; S_{B} i\right)=K=2\left(S^{2} \quad S_{A}^{2} \quad S_{B}^{2}\right)$. The lowest lying triplet $f 1 ; S^{z} ; 1 ; 1 i ; S^{z}=0 ; 1 \mathrm{ghasa}$ gap, $=K$, to the ground state $j 0 ; 0 ; 1 ; 1 i$. Since there is a further gap,
${ }^{0}=K$, to the higher excitations, we attem pt to obtain the instabilities of the PRVB phase by using a restricted quadrum er-boson $m$ ethod, om itting all the higher excitations on the quadrum ers. H ence, the spin- $1 / 2$ degrees of freedom on each quadrum er are expressed by bosonic operators on the restricted $H$ ilbert space,

$$
\begin{aligned}
& \text { jisi }=s^{y}-j 0 i=j 0 ; 0 ; 1 ; 1 i ; \\
& \jmath_{+} i=t_{+}^{y}-j i=11 ; 1 ; 1 ; 1 i ;
\end{aligned}
$$

$$
\begin{align*}
& \text { 夫 } i=t^{y}-j i=1 ;+1 ; 1 ; 1 i \text { : } \tag{6}
\end{align*}
$$

From the action of the spin operators $S_{i}, i=1 ;::: ; 4$ in the restricted $H$ ilbert space, the follow ing representation can be deduced [1d]

$$
\begin{align*}
& S_{i}^{z}=\frac{1}{4} t_{+}^{y} t_{+} \quad e^{y} t \quad \frac{(p}{p} \frac{1)^{i}}{6} t_{0}^{y} s+s^{y} t_{0} ; \\
& S_{i}=\frac{1}{2^{p} \overline{2}} t^{y} t_{0}+t_{0}^{y} t \quad \frac{(1)^{i}}{p} t^{y} s \quad s t \quad: \tag{7}
\end{align*}
$$

In the restricted H ilbert space, the hard-oore constraint $(\underline{4})$ is now obeyed on each quadnum er. Expressing the H am iltonian (1) in term s of the quadrum er-boson operators, a bosonic H am ittonian, $\mathrm{H}^{\mathrm{P}}=\mathrm{H}_{0}^{\mathrm{P}}+\mathrm{H}_{\mathrm{I}}^{\mathrm{P}}$, is obtained w ith a noninteracting diagonal part

$$
H_{0}^{P}=K^{X} \quad 2 \mathrm{~s} s \quad t^{\mathrm{y}} \mathrm{t}_{\text {; }}+t_{; 0}^{\mathrm{y}} \mathrm{t}_{; 0}+\mathrm{t}^{\mathrm{Y}} ; \mathrm{t} ; \quad \text {; }
$$

and a quartic scattering part $H_{I}^{P}$. Here the sum extends over the square lattioe of quadrum ers form ed by the $K$ bonds in Fig. 1. Follow ing the decoupling procedure already used in the dim er-boson approach, the follow ing threefold degenerate triplet excitation spectrum is obtained in the $P R V B$ regim $e$,

$$
!\left(k_{P}\right)=\begin{array}{llll}
\mathrm{K} & \mathrm{~K} & \frac{2}{3}(2 J & \left.J^{0}\right)\left(\operatorname{cosk}_{\mathrm{x}}+\operatorname{cosk}_{\mathrm{y}}\right)
\end{array}:
$$

Them inim um ofthis spectrum is located at $k_{P}=(;)_{P}$ when $J^{0}>2 J$, and the gap vanishes for $J^{0}>3=4(K+$ $2 \mathrm{~J})$, corresponding again to the order depicted in F ig. 1. Furtherm ore, for $J^{0}<2 J$ the $m$ inim um is located at $k_{P}^{0}=(0 ; 0)_{P}$, and the gap is again closed for $\mathrm{J}^{0}<$ $2 \mathrm{~J} 3=4 \mathrm{~K}$. In this regim e the m odelbecom es long-range N eel-ordered.

U pon com paring the ground state energies from the dim er- and the quadrum er-boson approach inside the com $m$ on range of stability, we can obtain the direct rst order transition line betw een the D RVB and PRVB spin liquid phases. [1] ]

FIG.2. Phase D iagram of the quadrum erized ShastrySutherland m odel. O rdered phases are characterized by the ordering $w$ ave vectors in the boson representations. Solid lines indicate second order transition lines, and the dashed line the rst order transition. A lso shown are points on the phase boundaries from quantum $M$ onte $C$ arlo (circles), $[4,13]$ exact diagonalization (squares, and triangles), and series expansion (diam ond). [12] D ashed-dotted lines are guides to the eye. The increm ent of the param eter scan in exact diagonalization was $(J=K)=0: 1$ [ $\left.\left(J^{0}=K\right)=0.2\right]$ for the $(;)_{P}\left[(0 ; 0)_{P}\right]$ phase boundary.

The overall phase diagram is shown in Fig. 2. The spin liquid phases are characterized by the corresponding RV B -like state, while we label the long-range ordered phases by the ordering wave vectors in the boson operator approaches. Furthem ore, solid lines represent second order phase transitions, w hereas the dashed line indicates the rst order transition line.

The $N$ eel-ordered phase $(0 ; 0)_{P}$ extends up to rather large frustration, $w$ th a largest extend of $\left(J^{0}=J\right)_{m}$ ax 12 along the Shastry-Sutherland line ( $J=K$ ). On the other hand, the largest extent of the ( ; ) P phase, for $J^{0}=K \quad 1: 3$ is bound by $(J=K)_{n}$ ax $0: 55$ from exact diagonalization. This di erence can be traced back to
the ratio of the number of frustrating couplings to the num ber the in itial couplings, which is $1: 4 \mathrm{w}$ hen starting at $J^{0}=0$, but $2: 3$ upon starting at $J=0$.

Furtherm ore, from the phase diagram in Fig. 2, we nd that the DRVB phase of the $1 / 5$-th depleted square lattice is adiabatically connected to the exact dimer VBS phase of the standard Shastry-Sutherland model (the dim er VBS state fails to be an exact eigenstate for $J \in K)$. On the other hand, the DRVB phase is not adiabatically connected to the PRVB, as expected on topological grounds. [2] $\left.1_{1}^{1}\right]$ H ence, we nd a rst order phase transition separating the two spin liquid phases beyond the regim e of the ( ; ) P phase.
$W$ hen tuming to the case $J>K$, the phase diagram show $n$ in $F$ ig. 2 is obtained upon interchanging $J$ and $K$, due to the invariance of the H am iltonian in Eq. (1) under the exchange ( $J \$ K$ ). Furtherm ore, we label the plaquette RVB-like phase for $J>K$ by $P R V B{ }^{0}$, since now singlets are predom inantly form ed on a di erent set of quadrum ers than in the PRVB phase.

## III. EXACTDIAGONALIZATION STUDIES

W e inchude in $F$ ig. 2 the positions of quantum critical points along the unfrustrated lines, obtained by quantum $M$ onte C arlo. [4] 1 above $m$ ean- eld theory. To extend the num erical analysis into the frustrated regim e we have perform ed exact diagonalization studies on clusters w th $\mathrm{N}=8 ; 16 ; 32$ spins, using periodic boundary conditions, along various lines in the phase diagram. $W$ e determ ine the nite size values of the order param eter, $M^{0}$, de ned by $\left[{ }_{2}^{2} \overline{0}_{1}^{\prime}\right]$

$$
\begin{equation*}
M^{\complement}(\mathbb{N})=\frac{1}{N(\mathbb{N}+2)}{ }^{*} \quad{ }_{i} \quad{ }_{i} S_{i} \quad: \tag{9}
\end{equation*}
$$

H ere $i$ takes on the values 1 at site $i$, according to the pattem in $F$ ig. 1 for the ( ; $)_{P}$ phase or the standard N eel-order for the $(0 ; 0)_{P}$ phase, respectively. U sing the $n$ ite-size data we determ ine $M{ }^{0}$ from the scaling law [2d]

$$
\begin{equation*}
M^{0}(N)=M^{0}+\frac{C_{1}}{N^{1=2}}+\frac{C_{2}}{N}: \tag{10}
\end{equation*}
$$

For exam ple, in $F$ ig. 3 we show results obtained along the line $J^{0}=1: 3$, where quantum $M$ onte $C$ arlo sim ulations at $J=0$ gíve a $m$ axim um $m$ om ent of $M{ }^{0} 0: 23$. [4]'] W thin exact diagonalization we can reproduce this value, and furthem ore observe a sm ooth decrease in $M{ }^{0}$ upon increasing the frustration, up to a criticalpoint at $J=K \quad 0: 55$, where we enter into the spin liquid regim e. Proceeding in a sim ilar fashion we obtain the critical points depicted by squares in $F$ ig. 2. M oreover, along the line $\mathrm{J}^{0}=2 \mathrm{~J}$ no nite order param eter was obtained after nite size scaling.

FIG.3. Evolution of the order param eter of the $(;)_{P}$ phase upon increasing $J=K$ for $J^{0}=K=1: 3$. The inset showns the nite size data obtained for $\mathrm{N}=8 ; 16 ; 32$ at $\mathrm{J}=\mathrm{K}=$ $0 ; 0: 1 ;::: 0: 6$, (top to bottom ).

The two spin liquid phases cannot be separated w ithin exact diagonalization using space group sym me try. $N$ am ely, upon increasing $J^{0}=K$ for a constant $J=K$, the representation class of the ground state does not change. $N$ evertheless, from the approxim ate slopes of the ground state energy vs. $J^{0}=K$ at constant $J=K$ in the regions of sm all and large $J^{0}=K$ respectively, we estim ated the rst order transition points indicated by triangles in F ig 2 .

C om paring these num erical results $w$ ith the $m$ ean- eld calculations in the last section, we conclude that the boson operator approach gives a good qualitative account of the phase diagram of the quadrum erized SSM. N am ely, the characterization of the various phases and the location of the phase transition lines agree well w ith num erical results.

## IV. SHASTRY-SUTHERLAND M ODEL

In the quadrum er-boson approach we nd a nite window on the Shastry-Sutherland line ( $J=K$ ), where both plaquette spin liquid phases, PRVB and PRVB ${ }^{0}$, com earbitrary close to the $J=K$ line. $T$ his already indicates an interm ediate phase in the standard SSM betw een the N eel-ordered phase and the dim er VBS phase. Sim ilar conclusions were obtained in a eld theoretical study of a generalized SSM, which does not break the sym $m$ etry needed by the dim er VBS state to be an exact eigenstate. [11] W e now focus on this interm ediate regim e in the standard SSM.
$T$ here has recently been considerable interest in the nature of the interm ediate phase. In the large spin, classicallim it the system retains $N$ eel-order for $J^{0}=J \quad 1$ and is helically ordered otherw ise, w ith a tw ist betw een next
nearest neighbour spins of $q=\arccos \left(J=J^{0}\right)$. U sing Schw inger boson m ean- eld theory, A lbrecht and M ila predicted the existence of a helical phase separating the dim er VBS and the ordered phase also for the spin $-1 / 2$ case, in a range $1: 1<J^{0}=J<1: 65$. [8] F ield-theoretical studies by C hung, $M$ arston, and Sachdev for a generalized spin-S m odelw ith $S p(2 N)$ sym $m$ etry suggest the helical order to occur in a larger range, 1:02 < $\mathrm{J}^{0}=\mathrm{J}<2: 7$, at $S=1=2$. [1] 10$]$ Furtherm ore, this approach predicts a phase w ith plaquette order in the extrem equantum lim it, $1=S>5$. Indeed, using series expansions around the plaquette lim it of Eq. (1), K oga and $K$ aw akam i found the interm ediate phase in a range 1:16 $<J^{0}=J<1: 48$ to be adiabatically connected to the PRVB phase. [d] H ow ever, extended series expansions by $W$ eihong, $O$ itm aa, and H am er lead to di erent conchusions. 12 l They suggest the PRVB phase to becom e unstable before the Shastry-Sutherland line is reached and found a colum nar dim er phase to be a possible candidate for the interm ediate phase.

FIG.4. Ground state energy per site of the Shas-try-Sutherland $m$ odel from exact diagonalization of clusters w ith $\mathrm{N}=16$ (squares), 20 (triangles), 24 (diam onds), and 32 (circles) sites. The solid line is a guide to the eye, and the dashed line is the exact dim er VBS state energy.

H ere, we perform exact diagonalization studies on clusters w ith up to 32 sites, signi cantly beyond the largest cluster sizes studied so far (24 sites in R ef. [2]']). In Fig. 4 we show the ground state energy of the SSM close to the transition into the dim er VBS state for various cluster sizes. T he solid line show s our results for the 32 site cluster, whereas other sizes are represented by sym bols. In addition, the energy of the dim er VBS state is shown by the dashed line. D ue to the di erent sym $m$ etry of the various chisters, the ground state enery per site does not show a m onotonous nite size dependence. N evertheless, independent of the cluster size we nd the system to be $w$ ithin the dim erVBS for $J^{0}=J>1: 5$, consistent $w$ ith the
upper bound for the interm ediate phase given by K oga and $K$ aw akam i, but signi cantly below the values from the Schw ingerboson, and Sp (2N ) theory. From nite size analysis of the N eel-orderparam eter, we estim ate a upper bound for the ordered phase of $\left(J^{0}=J\right)_{m}$ ax $<1: 4$, consistent w th the series expansion value $\left(J^{0}=J\right)_{\mathrm{m} \text { ax }}=1: 2 \quad 0: 1$ [ $1 \overline{2}^{\prime}$ ']. M ore interestingly, for the largest cluster we nd a characteristic change in the curvature of the ground state energy, well before entering the dim er VBS. Hence, we conclude that characteristic features of the interm ediate phase could be retrieved from clusters with $\mathrm{N}=32$ sites in a range $1: 425<J^{0}=J<1: 475$.

In this regim ewe nd the spin-spin, or $2-$ point correlation function to decrease rapidly w ith distance, indicating the absence of antiferrom agnetic order.

TABLE I. D im er-dim er correlations $C^{4}(1 ; 2 ; k ; 1)$ in the ground state of the Shastry-Sutherland m odel on the 32 sites cluster at $J^{0}=J=1: 45$. T he labeling of the sites is shown in Fig. 5.

In order to test against the various proposed ground states, we m easure the dim er-dim er, or 4 -point correlation functions,

on the $N=32$ lattice in the above interaction range. In particular, we $x(i ; j)=(0 ; 16)$ and extend $(k ; 1)$ over all inequivalent $J$ bonds. The values obtained in the ground state for $J^{0}=J=1: 45$ are displayed in Table $I$, and illustrated in Fig. 5, which also show s the labeling of the sites.

FIG.5. D im er-dim er correlations in the ground state of the Shastry-Sutherland $m$ odel on the 32 sites cluster at $J^{0}=J=1: 45$. The reference bond is the bond $(0 ; 16)$. P ositive (negative) correlations are drawn as full (dashed) lines. The thickness of a line is proportional to the strength of the correlation. Short diagonal lines indicate the position of the $J^{0}$-dim er bonds.

W e obtain a clear signal in the dim er-dim er correlations that extends throughout the whole cluster, with a nite asym ptotic value approxim ately reached for the largerdim er-dim erdistances on the cluster. In the spatial distribution we furthem ore observe periodic oscillations, which re ect an underlying order of quadrum er-singlets, form ed predom inately on void squares (i.e. those squares not containing a diagonalbond).

For the SSM there are two equivalent con gurations w th quadrum er-singlet coverings residing on the two different subsets of void squares (form ed by the J or K bonds in F ig. 1, respectively). H ence, if the plaquettelike order in the 4 -spin correlation function survives quantum uctuations, indicative of a plaquette VBC, a tw o-fold degenerate ground state $m$ anifold $w$ illem erge in the therm odynam ic lim it. On a nite lattice this degen-
eracy is lifted, but a low -lying singlet state w ell inside the triplet gap and only slightly above the ground state energy is expected. $W$ e can obtain the quantum num bers of this singlet state from the follow ing sym $m$ etry considerations: The Shastry-Sutherland lattioe has a 44 m space group sym $m$ etry, $[2]=1]$ and the ground state of the 32 site cluster has $m$ om entum $k=(0 ; 0)$, and is invariant under the $=2$ rotations about the center ofany void square (i.e. s-w ave like). Furtherm ore, the tw o equivalent con gurations of quadrum er-singlet coverings are related by the re ections about either diagonal dim er axes, but are invariant under the $=2$ rotations and lattice translations. N am ely, they both reside already inside a single unit cell of the Shastry-Sutherland lattioe.

FIG.6. G round state energy, and low-lying singlet and triplet excitations in the $k=(0 ; 0)$ sector of the Shas-try-Sutherland $m$ odel on the 32 sites cluster. O pen sym bols represent singlet states, full sym bols triplet states. Circles denote states $w$ ith eigenvalues $R=2=1$ ( $s-w$ ave), squares denote $R=2=1$ ( $d$-w ave), and triangles $R=2=i$ (tw o-fold degenerate). T he solid line is a guide to the eye for the ground state, the dotted to the low est excited s-w ave state, and the dashed line the low est d-w ave state. T he D ashed-dotted line is the exact dim er VB S state energy.

H ence, a low-lying $s$ w ave sym $m$ etric singlet state $w$ ith m om entum $(0 ; 0)$ is expected to be included in the spectrum of the 32 site cluster in the regim e of the plaquette VBS phase. This state should furtherm ore show sim ilar dim er-dim er correlations as the absolute ground state.

In F ig. 6 we plot the ground state energy along with those of the low est excited singlet and triplet states for the 32 site cluster in the zerom om entum sector. $W$ e specify the transform ation properties of the various states under the $=2$ rotation by the eigenvalue $R=2=1$ ( $s-$ wave), 1 (d-wave), or $i$ (two-fold degenerate). See the caption of $F$ ig. 6 for a detailed account on the various used sym bols. In the regim e where we expect evidence for an interm ediate state we indeed nd various low -lying singlet states w ell inside the rather large triplet
gap. M oreover, there are two singlet states w th energies rather close to the ground state energy, one being a s-w ave, and the other a d-w ave state w th respect to the $=2$ rotations. W e furthem ore calculated the dim erdim er correlations for both states and nd for the swave state a sim ilar signal as for the absolute ground state. On the other hand, the d-w ave state does not show any pattem in the dim er-dim er correlations. $T$ his state does not seem relevant for the ground state of the system in the them odynam ic lim it. P resum ably it is related to low -lying excitations in the dim erVBS phase. [23, [2]

From the above we conclude that the low -lying s-w ave singlet state, having the right quantum numbers and dim er-dim er correlation, w illlbecom e degenerate $w$ ith the ground state upon increasing the cluster size to the innite lattice. B oth states then form the tw o-fold degenerate ground state $m$ anifold of a plaquette VBC in the therm odynam ic lim it. In $F$ ig. 7 a pictorialdescription of this ground state $m$ anifold is given.

FIG.7. Pictorial illustration of the variational ground state $m$ anfold of the Shastry-Sutherland $m$ odel in the plaquette VBC phase. Thick lines indicate four spins involved in a quadrum er-singlet.

Furthem ore, this ground state $m$ anifold is invariant $w$ th respect to lattice translations and the $=2$ rotations about the centers of the void squares, but each state spontaneously breaks the re ection sym $m$ etry about the diagonal axes along the dim er directions.

From our num erical results we can also exclude a colum nar dim er state, which would be four-fold degenerate and furtherm ore show a di erent pattem in the dim er-dim er correlations than depicted in $F$ ig. 5. [2] $]$

Further evidence for the relevance of the plaquette VBC in the interm ediate regim e of the SSM can be drawn from analogous results of recent studies on the spin-1/2 H eisenberg m odel on the checkerboard lattice. [24,251] In this m odel, diagonalbonds are again organized on a square lattioe in a pattem as to leave half of the squares void. N am ely, the underlying lattice is obtained by adding in an additionaldiagonalbond on each square on which a dim er bond is located in Fig. 1. A lso in the checkerboard lattice quadrum er-singlets form on the void squares, resulting in a two-fold degenerate plaquette VBC ground state $m$ anifold $w$ ith broken space group
sym $m$ etry. T he structure leading to frustration is rather sim ilar in both $m$ odels, and the system tries to $m$ inim ize frustration by form ing plaquette valence bonds on the void squares. D ue to the hom ogeneous axial couplings, this can be accom plished only upon spontaneously breaking the sym $m$ etry inherited from the underlying lattioe.

## V.CONCLUSIONS

In conclusion, we have studied the phase diagram of the quadrum erized Shastry-Sutherland $m$ odel. U sing bondoperatorm ethods and exact num ericaldiagonalization its phase diagram was established, which links the various results available for special lim iting cases of the m odel. The antiferrom agnetically ordered phase of the 1/5-th depleted square lattice $m$ odel is destroyed by $m$ odest frustration, whereas the $N$ eel-ordered phase extends up to rather large frustration. T here is a rst order transition line separating the di erent spin liquid phases, PRVB and D RVB, beyond the ordered phase. Furtherm ore, the D RV B is adiabatically connected to the dim erVBS phase of the SSM .

For the standard SSM there exists a nite region around $J^{0}=J=1: 45 \mathrm{w}$ here the system becom es a plaquette VBC w ith spontaneously broken space group sym $m$ etry, and a tw o-fold degenerate ground state $m$ anifold. Perturbing aw ay from the Shastry-Sutherland line, i.e. for $J \in K$, the symm etry is broken explicitly, and the system favors a unique ground state, nam ely the PRVB for $J<K$, and the $P R V B^{0}$ for $J>K$. Furthem ore, upon varying $J^{0}$ along the Shastry-Sutherland line, a rst order transition leads to the dim er VBS and a second order transition to the $N$ eel-ordered phase. $W$ ithin our analyticaland num ericalstudies we did not nd indications for further phases in the (quadrum erized) SSM.

Stabilization of a plaquette VBC phase in both the Shastry-Sutherland and the checkerboard lattice model agrees $w$ th the generic structure of the underlying frustrated lattice. H ow ever, in the SSM the VBC is unstable tow ards the dim er VBS upon increasing the diagonal coupling. For the checkerboard lattice $m$ odel the range of the VBC phase is still unkow $n$, and rem ains for further studies.

W e acknow ledge fruitful discussions with Stephan H aas, A ndreas H onecker, and B ruce N orm and. This work has been nancially supported by the Sw iss Nationalfonds.

N ote added. $\{$ A fter com pletion of this work A kihisa K oga, and N orio K aw akam ipointed us to $R$ ef. $\left[\overline{2}_{2}^{1}\right]$, where the phase diagram of the H am iltonian in Eq. (1) was studied using series expansion $m$ ethods. Their results are in perfect agreem ent w ith our calculations in sections II and III. H ow ever in []$\left._{1}\right]_{1}$ the VBC nature of the inter$m$ ediate phase in the Shastry-Sutherland $m$ odelw as not noticed.
