# P unctuated evolution for the quasispecies $m$ odel 

Joachim K nug and Christian K arl Fachbereich Physik，U niversitat E ssen， 45117 E ssen，G erm any<br>（M arch 22，2024）

#### Abstract

$B$ iological evolution in a sequence space with random tnesses is studied within Eigen＇s qua－ sispecies model．A strong selection lim it is em ployed，in which the population resides at a single sequence at all tim es．Evolutionary trajectories start at a random ly chosen sequence and proceed to the global tness $m$ axim um through a sm all num ber of interm ittent jum ps．The distribution of the total evolution tim e displays a universalpow er law tailw ith exponent－ 2 ．Sim ulations show that the evolutionary dynam ics is very well represented by a sim pli ed shell model，in which the sub－ populations at local tness $m$ axim a grow independently．The shellm odelallow sfor highly e cient sim ulations，and provides a sim ple geom etric picture of the evolutionary tra jectories．

B iological evolution often displays a punctuated dy－ nam ical pattem，in the sense that quiescent periods of stasis altemate $w$ th bursts of rapid change．A vari－ ety of $m$ echanism s for punctuation have been proposed， which operate on di erent levels of the tree of life． On the largest scales of $m$ acroevolution，coevolutionary avalanches $m$ ay play a role，which have been associated w ith self－organized criticality［ill］．On the level of pop－ ulations，punctuation due to rare，bene cial mutations has been observed in evolution experim ents w th bacte－ ria $\left[\frac{1}{2}\right]$ ．Sim ilar behavior has been found in sim ulations of RNA evolution，where stasis corresponds to di usion on a neutralnetw ork，and a punctuation event $m$ arks the transition to another netw ork of higher tness［⿶凵⿱一𧰨刂1］．

P ossibly the sim plest interpretation of punctuated evo－ lution is in term s of a hom ogeneous population，repre－ sented by a localized distribution in som e phenotypic or genotypic space，which evolves in a static，multipeaked tness landscape $\left[\begin{array}{ll}{[1]} \\ \hline\end{array}\right]$ ．U nder conditions ofstrong selection and $s m$ all $m$ utation rate，such a population $w$ ill rapidly climb a local tness $m$ axim um，where it then resides for a long time，until a rare，large uctuation allows it to cross the valley to a $m$ ore favorable peak．At least in the lim it of in nite population size $\bar{F}_{1}^{\prime} 1$ ，the $m$ athem atics of th is process is closely related to physicalproblem s such as noise－driven barrier crossing，tunneling［G］$\left[\frac{1}{]}\right.$ and variable－ range hopping $\left[\begin{array}{l}{[7]}\end{array}\right]$ ，and it is easy to show that the resi－ dence tim e at one peak can be vastly larger than the tim e required for the transition to the next［［G］．In a rugged tness landscape，the sequence of transitions form $s$ an evolutionary trajectory，which probes the distribution of tness peaks and the geom etry of the landscape．
In this Letter we investigate the statistics of such evo－ lutionary tra jectories in the fram ew ork ofE igen＇s quasis－ pecies m odel［9，${ }^{1}[1]$ ． W e consider a population of individ－ uals，each characterized by a binary genom ic sequence
of length $N$ ，which reproduce asexually and mutate in discrete timet．The total number of sequences is $S=2^{N}$ ．An individual with genotype leaves A（ ） －spring in the next generation，and point m utations oc－ curw ith probability persite and generation．In a m ean
eld approxim ation，which neglects nite population ef－ fects as well as nonlinear constraints on the population size，this leads to the evolution equations

$$
\begin{equation*}
z(; t+1)={ }^{X} A\left({ }^{0}\right) d\left(;^{0}\right)(1 \quad)^{N} d\left(;{ }^{0}\right) z\left({ }^{0} ; t\right) \tag{1}
\end{equation*}
$$

for the number $z(; t)$ of individuals of genotype， where $d\left(;{ }^{0}\right.$ ）denotes the H am m ing distance between sequences and ${ }^{0}$ ，i．e．the num ber of sym bols in which the two di er．

The tness landscape enters $[\bar{\square} \overline{1})$ through the choice of A（ ）．For single peaked landscapes，the $m$ odel is know $n$ to exhibit the error threshold phenom enon，in which a population which is concentrated around the tness peak \｛ the quasispecies \｛ becom es delocalized w ith increasing $m$ utation rate，increasing sequence length，or decreasing peak height $[1][1]$ ．Here we want to study the sudden transitions betw een the di erent quasispecies associated w ith the m ultiple peaks ofa rugged tness landscape $\left[\overline{1} \overline{2}_{2} 1\right.$ ． $T$ his punctuated behavior becom es $m$ ore pronounced the $m$ ore strongly the peaks are able to localize the pop－ ulation．We therefore pass to a strong selection lim it ［13ㄴㄹㅔ，which is m otivated by the zero tem perature lim it of the equivalent problem of a pinned directed polym er
 $\operatorname{asA}()=e^{\mathrm{kF}()}$ ，where k is an inverse selective tem per－ ature［15］．In the lim it k！ 1 the population variables take the form $z(; t)=e^{k E}(; t)$ and them utation rate per generation has to be scaled down as $=e^{k}$ for some constant $>0$. Then $(\underline{1})$ reduces to

$$
\begin{equation*}
\left.E(; t+1)=m \operatorname{axp}_{0} \mathbb{E}\left({ }^{0} ; t\right)+F\left({ }^{0}\right) \quad d\left(;^{0}\right)\right]: \tag{2}
\end{equation*}
$$

The tnesses $F$（ ） 0 are chosen random ly and in－ dependently from a distribution $p(F)$ ．The num erical sim ulations presented in this paper were perform ed w ith $p(F)=e^{F}$ ，but results for other distributions $w i l l$ be described as well．The value of is set to unity．

Evolutionary trajectories are generated as follow s．At time $t=0$ the population is placed at a random ly cho－
sen sequence ${ }^{(i)}$, corresponding to the initial condition $E\left({ }^{\text {(i) }} ; 0\right)=0, E\left(\right.$ (i) $\left.^{\text {(i) }} ; 0\right)=1$. Subsequently ${ }_{1}^{\prime}\binom{$ ( }{$\boldsymbol{r})}$ is iterated, and the position ( t ) of the globalm axim um ofe ( ; t ) is recorded; in the strong selection lim it, essentially the whole population resides at ( $t$ ) at tim et. The trajectory (t) diplays the expected punctuated pattem [13']. A fter the rst few tim e steps, it passes exclusively through local tness $m$ axim a. The transitions betw een di erent local m axim a are abrupt, and the tim e period spent at a given peak, as well as the probability for a peak to be visited by a trajectory w ith random starting point, increases strongly w th its tness. The end point of each trajectory is the global tness $m$ axim um of the landscape.

H ere we focus on two statisticalm easures of the evohutionary trajectories: The distribution $P(T)$ of tim es $T$ required to reach the global $m$ axim um, and the distribution $P(n)$ of the num ber $n$ of jum ps betw een local $m$ axim a that occur on the way. In $F$ igs' results for sequence lengths $\mathrm{N}=8$ \{ 17 are show n . T he data were averaged over $10^{5}$ trajectories, each evolving in a separate, independently generated tness landscape. To m ake the problem num erically tractable despite the exponential grow th of sequence space $w$ th increasing $N$, these sim ulations w ere carried out using a bocal version of the recursion relation $(\bar{Z})$, in which the $m$ axim ization on the right hand side is perform ed over nearest neighbor sequences $w$ ith $d\left(;^{0}\right) \quad 1$ only. This implies that at m ost one point m utation is allow ed per generation. T he full dynam ics $(\bar{Z})$ and the local version w ill be referred to as the global and the localm odel, respectively. The differences in behavior that arise due to the localrestriction will be explained below.

N otable features of the num erical results in $F$ ig igl include (i) a (roughly linear) increase of the typical evolution timew ith $N$, as represented e.g. by the $m$ axim um off ( T ), and (ii) a power law tailp ( T ) $\mathrm{a}(\mathbb{N}) \mathrm{T}$ with

2 for $T \quad N$. A carefil analysis of the data for di erent sequenœ lengths show s no system atic dependence of on N , and yields the overall best estim ate
$=2: 13 \quad 0: 04$. If it is assum ed that $=2$ exactly (see below), then the coe cient $a(\mathbb{N})$ of the power law scales w ith sequence length as a $(\mathbb{N}) \quad \mathrm{N}^{1: 7}$. The distribution of the num ber of jum ps in F ig ${ }_{2}^{\prime 2}$ is w ell tted by a G aussian. The $m$ ean num ber of jumps $n$ is $s m a l l$, and the variance $n^{2}<n$, indicating sub-Poissonian uctuations. In the (adm ittedly sm all) range of $N$ accessible to our sim ulations, the dependence on sequence length is reasonably w ell described by pow er law S , $\mathrm{n} \quad 0: 56 \quad \mathrm{R} \cdot \mathrm{F}^{73}$ and $\mathrm{n}^{2}$ 0:17 $\quad$ R $\mathrm{F}^{74}$.

To gain some insight into these results, we now introduce an approxim ation to ( $\overline{\underline{Z}})$ which allows for som e analysis, as well as for a much m ore e cient num erical schem e. T he evolutionary dynam ics ( $\overline{11}$ ) and ( $\overline{2})$ ) involves tw o distinct processes: The spreading of the population through sequence space by mutations, and the (expo-
nential) grow th of the localsub-populations by selection. O ur key assum ption is that the spreading part of the dynam ics is im portant only in the initialstages ofevolution, while the late stage can be described as a com petition betw een independently grow ing quasispecies associated $w$ ith di erent local tness $m$ axim a.

M ore speci cally, after the rst tim e step the recursion relation (2) w ith the initial condition localized at (i) yields a (logarithm ic) population distribution $\mathrm{E}(; 1)=$ $F\left({ }^{(i)}\right) \quad d\left(\right.$; $\left.^{(i)}\right)$ which is sym $m$ etric around (i) and linearly decreasing with increasing distance from (i). Thus at $t=1$ every sequence is seeded $w$ th a (possibly astronom ically sm all) population. The approxim ation consists of letting these populations evolve independently fort 2 , i.e. to replace ${ }_{(1)}^{(+1)}$ ) by the simple linear grow th law

$$
\begin{equation*}
E(; t)=E(; 1)+(t \quad 1) F(): \tag{3}
\end{equation*}
$$

Since E ( $; 1$ ) is constant on the shells of constant H am $m$ ing distance $d\left(\right.$; $\left.^{(i)}\right)=k$ to the initial population, for each shell only the sequence $w$ th the largest tness needs to be taken into account. The $N$ shell thesses can be generated directly from the distribution of the largest am ong ${ }_{k}^{N}$ exponential random variables, corresponding to the ${ }_{k}^{N}$ sequences contained in the shell. In this way the shellapproxim ation vastly reduces the com putational
 im ation works astoundingly well. For sequence lengths $\mathrm{N}=8$ and 10, for which a com parison is possible, the distributions P ( $T$ ) and $P(n)$ obtained (w ith little e ort) using the shell approxim ation are indistinguishable from those generated by the full m odel ( (ᄌ, ) w ith globalm axi$m$ ization.

The situation is more com plicated for the localm odel used in $F$ igs, $\overline{1} 1$, and $\overline{1}, \underline{1}$, because in that case the seeding stage takes $N$ tim e steps. This explains im $m$ ediately the appearanœ of a typicalevolution tim e of order $N$, which is absent in the globalm odel: On average, it takes $\mathrm{N}=2$ tim e steps before the global tness $m$ axim um has even been seeded. The seeding tim efor the shell at distance $d\left(\right.$; $\left.^{(i)}\right)=k$ is $k$. The shell approxim ation can be im plem ented only for tim es $t \quad k$, where linear grow th according to $E(; t)=E(; k)+(t \quad k) F()$ sets in. This is how ever less useful than ( $\overline{3} \overline{1}$ ), because the com putation of $E(; k)$ already requires the solution of a nontrivial optim ization problem : The population strength at the \seeding front" de ned by $d\left(\right.$; $\left.^{(i)}\right)=t$ is given by

$$
E(; \mathrm{t})=\max \mathrm{X}_{02}^{\text {" }} \mathrm{F}\left({ }^{0}\right) \quad \mathrm{t}_{\text {; }}
$$

where denotes a directed path of length $t$ from (i) to . A reasonable shell approxim ation for the localm odel (w hich is how ever not as accurate as in the global case) is obtained by treating the rst term on the right hand
side of $\left(\overline{4} \underline{L}^{-1}\right)$ as a constant, setting $E(; k)=k$ in shell k .

U sing ( $\overline{3}_{1}^{\prime}$ ), the totalevolution tim e T can be estim ated as

$$
\begin{equation*}
T \frac{\left[d ( ^ { ( f ) } ; ^ { ( \mathrm { i } ) } ) \quad \mathrm { d } \left(^{\left.\left.\left({ }^{(f 1)}\right)^{(\mathrm{i})}\right)\right]}\right.\right.}{\mathrm{F}\left({ }^{(\mathrm{f})}\right) \mathrm{F}\left({ }^{(\mathrm{f}}{ }^{1)}\right)} \text {; } \tag{5}
\end{equation*}
$$

where (f) denotes the global tness m axim um, and ( $£ 1$ ) is the last sequence visited before the globalm aximum is reached. $W$ e expect that ( ${ }^{(1)}$ is close in tness to the sequence w ith the second largest thess in the sys-
 the tness gap of the landscape, which we de ne as the di erence betw een the largest and the second largest of the $S$ tness values. To estim ate the num erator of ( ${ }_{(2)}{ }^{-1}$ ), wepote that $m$ ost sequences reside in a belt of thickness
$\overline{\mathrm{N}}$ around the m ean distance $\mathrm{N}_{\overline{\mathrm{p}}} 2$ from ${ }^{\text {(i) }}$, and
 that $\mathrm{T} \quad \overline{\mathrm{N}}=$. The inverse correlation betw een T and
for a given landscape has been explicitly veri ed in the sim ulations [1] [].

The distribution $P_{g}()$ of the tness gap can be com puted from order statistics []$\left._{1} \bar{T}_{1}\right]$. The distribution of evolution tim es then becom es $P(\bar{T}) \quad\left(\bar{N}=T^{2}\right) P_{g}(\bar{N}=T)$, which displays a power law tail with exponent $=2$ for $T \quad \bar{N}$ and prefactor $a(N) \quad \bar{N} P_{g}(0)$. The $T^{2}$-decay is universal, because $P_{g}(0)$ is alw ays nite and nonzero [131]. It follow $s$ from the explicit expression that $P_{g}(0) \quad\left(F_{m a x}(S)\right)^{1}$, where $F_{m a x}(S)$ denotes the standard deviation of the $m$ axim um $F_{m a x}(S)$ am ong the $S$ independent tness values. For the exponential
thess distribution $P_{g}()=\exp (\quad)$ independent of $N$ so that a $(\mathbb{N}) \quad \bar{N}$. In contrast, for fat tailed tness distributions such as power law s, a $(\mathbb{N})$ decreases with increasing $N$. These predictions are well con m ed by sim ulations of the global shell m odel.

Repeating the argum ent for the shell approxim ation to the local m odel described above, one nds P (T) $a(\mathbb{N}) \mathrm{T}^{2} \mathrm{w}$ th $\mathrm{a}(\mathbb{N}) \quad \overline{\mathrm{N}}_{\mathrm{h}}^{\mathrm{F}} \mathrm{m}$ ax $(\mathrm{S}) \mathrm{iP}_{\mathrm{g}}(0)$. For the exponential distribution $h F_{m}$ ax $(S) i=\ln S \quad N$, hence $a(\mathbb{N}) \quad N^{3=2}$, which is consistent $w$ ith the num ericalestim ate quoted above. W e conclude that the asym ptotic value of the evolution tim e exponent is $=2$ in allcases, and attribute the deviations found in the data in $F$ ig ${ }_{\underline{1}}^{\prime 1}$ to short tim e corrections originating in the seeding stage.

W thin the shell $m$ odel, the problem of determ ining the number of jumps along an evolutionary trajectory has a simple geom etric interpretation. Eq. ( ${ }_{1}$ in ) de nes a fam ily of $N$ straight lines in the ( $t$; ) -plane, one for each shell. The intercept of the line corresponding to shell $k$ is $F$ ( ${ }^{(i)}$ ) $k$ and its slope is the shell tness $F_{k}$, i.e. the largest am ong ${ }_{k}^{N}$ independent tness values. The evolutionary tra jectory (t) then corresponds to the upper envelope of this fam ily of lines, and the num ber of jum ps is the num ber of comers of this random polygon.

It follow s im m ediately that the num ber of jum ps is always sm aller than N. To go beyond this trivial bound is not easy, because the shell thesses are not identically distributed, i.e. the distribution of $\mathrm{F}_{\mathrm{k}}$ depends on k . For large $N$ the globalm axim um is certain to lie near the shell $\mathrm{k}=\mathrm{N}=2$, so that $\mathrm{n} \quad \mathrm{N}=2$. If one assum es that only sequences $w$ ith tnesses com parable to the the globalm axim um, which reside in the belt around $k=N=2$, contribute to the trajectory, then $n \quad \bar{N}$. Sim ulations of the global shellm odel yield $n \quad N^{0: 60}$ and $n^{2} \quad N^{0: 72}$ for $4 \mathrm{~N} \quad 29$, but the data are not inconsistent w ith a linear dependence on N .

M ore progress is possible for a sm pli ed shellm odel in which the shell tnesses are identically distributed (this corresponds to a one-dim ensional sequence space). Suppose that at som e tim e the population resides in shellk. The next jump then occurs to the shell $k^{0}>k$ for which (i) $\mathrm{F}_{\mathrm{k}}^{0}>\mathrm{F}_{\mathrm{k}}$ and (ii) thetimet $\left(\mathrm{k} ; \mathrm{k}^{0}\right)=\left(\begin{array}{ll}0 & \mathrm{k}\end{array}\right)=\left(\mathrm{F}_{\mathrm{k}}^{0} \quad \mathrm{~F}_{\mathrm{k}}\right)$ at which the two lines cross is $m$ inim al am ong all such $\mathrm{k}^{0}$. If the second requirem ent is ignored and one sim ply choses the next shellw ith $k^{0}>k$ and $F_{k}^{0}>F_{k}$, the problem reduces to that of record dynam ics, for which the num ber of jum ps is P oisson distributed w th $m$ ean $\ln N$ [ 1 ㅇ́́]. Since the greedy record algorithm evidently produces $m$ ore jum ps than the original dynam ics, the $m$ ean num ber of jum ps in the uniform shellm odel is bounded from above by $\ln N$, independent of the thess distribution. Sim ulations of this m odel indicate that in general $\mathrm{n} \quad \ln \mathrm{N}$, where the coe cient $<1$ depends on the extrem alstatistics of the tness distribution. Speci cally, we conjecture that $=1=2$ for distributions sim ilar to an exponential, $=(1)=(21)$ for power law distributionsp $(F) \quad F^{(+1)}$, and $=(2+)=(3+2)$ for bounded distributionsw ith $\mathrm{p}(\mathrm{F}) \quad\left(\mathrm{F}_{0} \quad \mathrm{~F}\right), \mathrm{F} \quad \mathrm{F}_{0}$.

In conclusion, we have explored the statistical properties of evolutionary trajectories in a sequence space equipped w th a rugged tness landscape. The sim ple but highly accurate shell approxim ation elucidates the interplay of the geom etry of sequence space and the extrem al statistics of thess values, and allow s for e cient num erical investigations. It seem s w orthw hile to extend these studies to correlated tness landscapes and di erent types of graphs, w ith the aim of using evolutionary tra jectories as a m eans to characterize the geom etry of generaloptim ization problem s.
