(dated: submitted to PRB on 3 May 2002)

We present a detailed quantitative comparison between theoretical calculations of the local density of states and recent experimental measurements of scanning tunneling spectra around Ni impurities in $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$. A double-peak structure on the hole side of the spectrum at the Ni site is identified as the spin-split van Hove singularity in the band structure. The Ni atom induces local changes in hopping matrix elements comparable in size to the induced on-site spin-dependent potential. We find evidence from the measurements of order parameter suppression in the vicinity of the Ni impurity. These extracted impurity parameters can be of use in quantitative calculations of macroscopic response properties, such as the AC conductivity.

PACS numbers: 74.25.Jb, 74.80.-g

The response of a superconductor to impurities can determine several macroscopic electromagnetic properties, such as the magnetic penetration depth and high frequency losses.¹ For high-temperature superconductors it is advantageous to study the impurity problem in real space rather than in momentum space,² not only because the impurities destroy the translational invariance, but also because these doped systems are intrinsically inhomogeneous.³ High-quality electronic spectra, using the technique of scanning tunneling microscopy (STM), around individual impurity atoms in superconducting $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ have recently become available.^{4,5} Quantitative comparison between calculations of the local density of states (LDOS) and these STM measurements can lead to effective impurity parameters that are useful for calculating macroscopic properties.

A number of theoretical studies of the STM spectra near impurities in d-wave superconductors have already been carried out by various authors.^{2,6,7,8,9,10,11,12} These previous studies focused on qualitative features, such as the existence of quasiparticle resonances, the spatial structure of the resonances, and the differences among systems with various pairing symmetries. Often the model for an impurity only consisted of effective potentials at the impurity site, or relied on an unrealistic band structure for the host superconductor. There are still significant quantitative disagreements between the theoretical and experimental LDOS.^{10,11,12} Of the types of impurities and defects for which high-quality STM spectra are available, the Ni impurity provides a good opportunity to resolve some of these issues. Because the perturbation to the local environment caused by a Ni impurity is weak,^{5,13} we find that, with some extensions to the potential model the STM spectra can be well reproduced by our calculations. In addition to the short-ranged potentials at the impurity site, we also include the change of the hopping matrix elements from the impurity site to its nearest neighbors, and the suppression of the order parameter.

We also find an interesting interplay between the underlying band structure and the superconducting coher-

ence peak near a Ni impurity. In the spectrum of the Ni site there is a large peak on the hole side (below the chemical potential), right outside the gap edge. We find that this peak, previously thought as the remnant of the coherence peak, is largely contributed by a density-of-states peak in the underlying band structure. One special and important feature of hole doped cuprate superconductors is that a van Hove singularity is close to the Fermi level. It has been suggested by various authors^{14,15,16,17,18,19,20} that the existence of the van Hove singularity could affect the mechanism of superconductivity, and also account for the unusual normal state properties. The existence of such a density-of-states peak has received direct support from experiments using angle-resolved photoemission spectroscopy (ARPES).^{21,22} Despite this density-of-states peak (aside from the coherence peaks) in the superconducting state has never been directly reported in tunneling experiments. Traces of this feature were suggested to explain the asymmetry of the coherence peaks,^{23,24} and the sharpness of the coherence peaks. However, no specific qualitative influence of a van Hove peak on the midgap impurity resonances of a particular impurity has been considered.²⁵

We find that the Ni impurity offers a novel probe of the van Hove peak. The van Hove singularity is likely very close to the Fermi level, therefore, in the superconducting state the van Hove peak cannot be resolved from the coherence peak. The Ni impurity will locally suppress the coherence peak, but only weakly perturb the underlying band structure. As a result, the van Hove peak shows up unmasked in the spectrum at the impurity site.

Our calculation is based on the following tight-binding Hamiltonian,

$$\begin{aligned}
 H = & \sum_{ij} (t_{ij} + t_{ij}^*) c_i^\dagger c_j \\
 & + \sum_{ij,ji}^{\text{hijji}} \left((t_{ij} + t_{ij}^*) c_i^\dagger c_{j\#}^\dagger + (t_{ij} + t_{ij}^*) c_{j\#} c_i \right) \\
 & + (V_0 + V_S) c_0^\dagger c_0 + (V_0 - V_S) c_{0\#}^\dagger c_{0\#} ; \quad (1)
 \end{aligned}$$

FIG. 1: A schematic diagram showing our model of a Ni impurity on the CuO plane. Parameters extracted from fitting to the data are listed on the right.

where i and j label sites (the impurity resides at site 0), and σ labels spin. The hopping matrix elements, t_{ij} , are taken from a one-band parameterization of the ARPES data.²⁶ The numerical values in units of meV are 148.8, 40.9, 13, 14, and 12.8 for the hopping to the first five nearest neighbors. The measured value for the gap maximum Δ_0 at a site away from the impurity is 28 meV.⁵ The order parameters, Δ_{ij} , are assumed to be real, and to have d-wave symmetry. They are only non-zero on the bonds between two nearest-neighbor sites, and $\Delta_{i,i+\hat{x}} = \Delta_{i,i+\hat{y}} = \Delta_0 = 4$. The momentum-dependent order parameter resulting from a homogeneous system with these Δ_{ij} is $\Delta_k = (\Delta_0/2)(\cos k_x - \cos k_y)$, where the lattice spacing between two Cu atoms is unity.

Because the experiments were carried out at low temperatures, the spin degree-of-freedom of the magnetic Ni impurity is assumed to be completely frozen. At the Ni site, we use a potential that consists of a magnetic part, V_S , and a non-magnetic part, V_0 . It is found that the Ni impurity induces a change in the hopping, t_{ij} , to the nearest neighbor sites, and a suppression of the order parameter magnitudes, Δ_{ij} , on the four bonds connected to the Ni site, and on the other twelve bonds connected to the nearest neighbor sites. A schematic diagram of our model and the fitting parameters used for the Ni impurity are shown in FIG. 1.

Calculations presented here are based on a Koster-Slater technique.^{2,27,28} The homogeneous Green's function, $g(r_i; r_j; !)$, in the Nambu formalism is first constructed with a 1 meV quasiparticle linewidth. In the presence of an impurity modeled by V , the Gor'kov equation, $G = g + gVG = (I - gV)^{-1}g$, is solved by numerically inverting the matrices. The LDOS is the imaginary part of the Green's function, $\rho(1) = \text{Im}[G_{11}(r_i; r_i; !) - G_{22}(r_i; r_i; !)]$.

In the following, we will discuss how various parameters influence our calculations. Although six parameters including the chemical potential are introduced in the model, there are particular features in the LDOS spectra associated with each of them. This allows us to determine each parameter largely independently from the others.

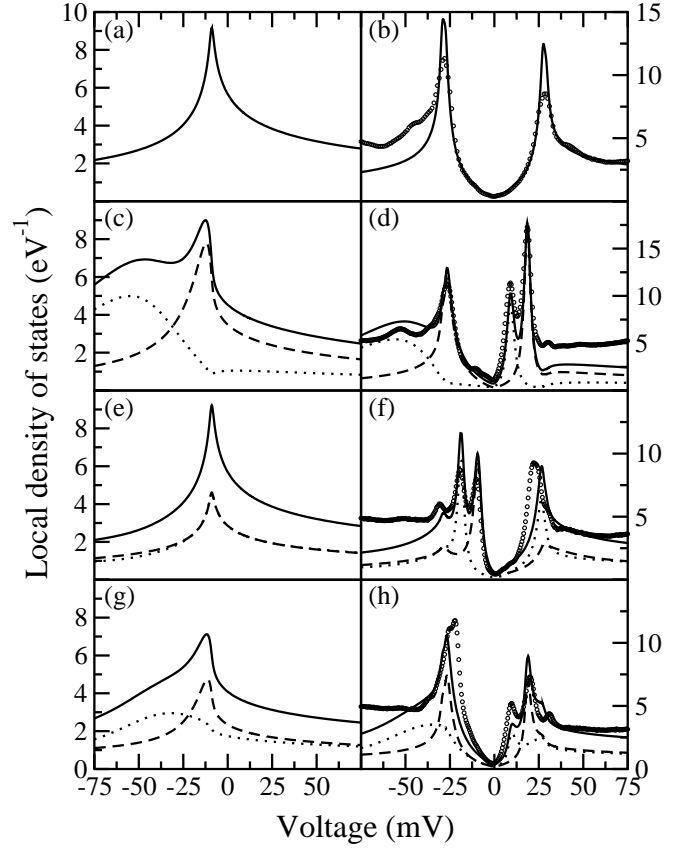

FIG. 2: LDOS spectra at various sites near a Ni impurity. The left panels show the spectra in the normal state. The right panels show the spectra in the superconducting state. Solid lines show the calculated results. Dashed and dotted lines show the two spin components. (a) and (b) are the spectra at a site about 30 Å away from the Ni impurity. (c) and (d) are the spectra right at the impurity site. (e) and (f) are the spectra on the nearest neighbor site. (g) and (h) are the spectra on the second nearest neighbor site. Open circles (○) show the STM data.⁵ The data was rescaled by a constant factor identical for all the spectra.

Let us first consider the chemical potential. From the ARPES parameterization,²⁶ the chemical potential for an optimally doped sample is 130.5 meV. However, we know from STM measurements that the doping concentration is locally varying, and is correlated with the superconducting gap magnitude.³ A region with a gap magnitude of 28 meV is overdoped. The fit to STM spectra is optimal if the shift in chemical potential relative to the optimally doped region is about 25 meV. This amount of shift changes the location of the van Hove singularity from 34 meV to 9 meV below the Fermi level, shown in FIG 2(a) for $\Delta_{ij} = 0$.²⁹ In the superconducting state the van Hove singularity cannot be resolved from the coherence peak at the hole side, shown in FIG 2(b). The chemical potential shift also sharpens the coherence peaks, and contributes to the asymmetry between the two peaks. Although not direct evidence for the van Hove singularity

FIG. 3: Evolution of the spectra as a function of distance from the Ni atom. Left panel shows the calculations, and the right panel shows the data from Fig. 4 in Ref. 5. The spin splitting of the resonance peaks inside the gap is constant as one moves away from the impurity site. The spin splitting of the van Hove singularity decreases as the distance increases.

in STM, the agreement between the calculations and the measurements is certainly improved.

We now describe the modeling of the Ni impurity focusing first on the single-site potential model with only the on-site potentials, V_0 and V_S . For a weak potential, the main effect of these potential is to set the energies of the resonances. Since the resonance peaks for Ni are at 9.2 and 18.6 meV, and the perturbation from Ni is weak, both $V_0 + V_S$ and $V_0 - V_S$ should be negative. Our V_0 does not differ greatly from that found in a simple model.³⁰ The two on-site parameters, V_0 and V_S , are both required to fit the energies of the two resonance peaks.³¹ Note that we have no control over the peak height or width in the spectra using this simple model. We find, due to extended states within the gap, that the resonance peaks will be broader than the coherence peaks. In the observation, however, the width of the resonance peaks appears comparable, or even sharper, than the coherence peaks.

In order to reduce the coupling to the extended states and increase the localization of the resonance states, we then assume that the hopping to the nearest neighbor sites, t_{01} , is reduced. With only a 20% change in the nearest-neighbor hopping, we can reproduce the linewidth of the resonance peaks. V_0 and V_S must be ad-

justed slightly when t_{01} is introduced in order to keep the resonances at the fixed energies. Our calculations show that the magnitudes of the on-site potentials change to even weaker values, and characterize an even weaker impurity potential. Using these three parameters for calculating the effect of a Ni impurity in the normal state (shown in FIG 2(c)), one can see that the band structure is not highly distorted. The van Hove peak remains reasonably sharp, and splits into two spin components. Comparing 2(c) to the superconducting state, shown in FIG 2(d), we can identify the two peaks on the hole side, right outside the gap edge, as the spin-split van Hove peaks. A similar connection between the normal state electronic structure and an impurity's influence on the superconducting state has been identified in calculations for impurities in s-wave superconductors.^{27,28} Another distinction between the midgap resonances and the van Hove peaks is that the spin splitting of the resonance peaks inside the gap remains independent of distance from the impurity site. The spin splitting of the van Hove singularity, however, decreases as the distance increases.

Once the large peak at the hole side was identified as the van Hove peak, a noticeable disagreement between the calculation and the data became apparent. The calculated relative energy difference between the resonance peaks and the van Hove peaks is somewhat larger than the observed value if the gap maximum is constant everywhere. In the d-wave superconducting state, the position of the van Hove peak is dominated by the gap edge. One cannot increase the agreement by tuning V_0 because that shifts all peaks almost an equal amount of energy. We could obtain good agreement if the gap maximum were about 22 meV instead of 28 meV. In principle using self-consistent calculations can account for the effect, however, the self-consistency conditions involve the pairing mechanism, which is controversial. Taking a phenomenological approach, we can identify the suppression of the order parameter around the impurity from the data. This then becomes a constraint on pairing theory. We find that the parameter is locally suppressed more than 50% (See FIG. 1).

So far, we were only fitting the spectrum right at the Ni site. Nevertheless, good agreement in spatial structure is also obtained. Detailed comparisons for the spectra on neighboring sites are shown in FIG. 2(e)-(h), the spatial decay of the resonance peaks is shown in FIG. 3, and the spatial maps at given energies are shown in FIG. 4. These are direct comparisons with the data in FIGs. 2 & 4 in Ref. 5.

Two key additional features are found from the spatial structure. The first one is that the hole component of the resonance has d-wave symmetry.^{2,13} The second is that the perturbation, due to the van Hove singularity, is strongest along the diagonals of the lattice. At given energy, the secondary peaks are always located at the next-nearest rather than the nearest neighbor sites relative to the main peaks. This is because, around the Fermi level, the saddle points that give rise to the van Hove sin-

FIG. 4: (color) Spatial structure of the LDOS around a Ni impurity in the normal state at (a) 15 meV, (b) 50 meV (near van Hove peak positions in FIG. 2(c)), and in the superconducting state at (c) +9 meV, and (d) -9 meV. The Wannier function is assumed to be a Gaussian with a width of half the lattice spacing. The LDOS is shown in logarithmic scales and in units of eV^{-1} . The lattice orientation in (c) and (d) needs to be rotated by 45° when compared to Fig. 2 in Ref. 5.

gularity in the density of states are near the $(\pm 1; 0)$ and

$(0; \pm 1)$ points in momentum space. The main contribution to the real space Green's function largely comes from these high density-of-states regions,

$$g(\mathbf{r}_i; \mathbf{r}_j; !) = \sum_{\mathbf{k}} \frac{d^2 k}{(2\pi)^2} e^{i\mathbf{k} \cdot (\mathbf{r}_i - \mathbf{r}_j)} g(\mathbf{k}; !) : \quad (2)$$

For $\mathbf{r}_i - \mathbf{r}_j = (\pm 1; \pm 1)$ the four regions add up constructively, while for $(\pm 1; 0)$ or $(0; \pm 1)$, the contributions from $(\pm 1; 0)$ cancel with those from $(0; \pm 1)$. As a result, $|g(\pm 1; \pm 1; (0; 0); !)| \gg |g(\pm 1; 0; (0; 0); !)|$ for energies near the chemical potential. This is also consistent with the larger spin splitting of the van Hove peak at the second nearest neighbors compared to the nearest neighbors.

In this study we have assumed that the STM spectra are directly related to the electronic structure of the Cu{O} plane regardless of the presence of the intermediate Bi{O} plane. As was argued in Ref. 5, the energies and linewidths of the resonances should be the same. We find the principal effect of a d-wave filter³² on our parameterization is to (roughly) change the sign of V_0 . Therefore, the evidence for the reduction of hopping, and suppression of the order parameter are still clear.

In summary, the presence of a Ni atom on the Cu{O} plane produces a weak perturbation to the system. We show direct evidence for a density-of-states peak in the STM measurements and local suppression of the order parameter. The suppression of the order parameter can constrain the self-consistency condition and thus the pairing mechanism.
