A b stract. We consider a growing network, whose growth algorithm is based on the preferential attachment typical for scale-free constructions, but where the long-range bonds are disadvantaged. Thus, the probability to get connected to a site at distance d is proportional to defined by where is a tunable parameter of the model. We show that the properties of the networks grown with < 1 are close to those of the genuine scale-free construction, while for > 1 the structure of the network is vastly dierent. Thus, in this regime, the node degree distribution is no more a power law, and it is well-represented by a stretched exponential. On the other hand, the small-world property of the growing networks is preserved at all values of .

PACS numbers: 89.75.k, 05.50.+q, 89.75.Hc

Complex weblike structures (the small-world or scalefree networks) have recently become an object of extensive investigation, and in the last years a great success in understanding the properties of these structures was achieved (see Ref. [1] as a review). A part from appealing m athematics, this recent interest is due to the fact that many natural and technological systems, like polym er networks [2], the science collaboration network [3{5], or networks of chemical reactions in a living cell [6{8] seem to be organized according to some internal principles. Thus, the Internet [9], the network of hum an sexual contacts [10] or the W W W [11] possess a similar structure, e.g. are they all based on the preferential attachment of the newly introduced nodes to the highly connected old ones. A 11 these networks show the small-world property: the typical distance (in terms of the number of intermediate connections) between two nodes grows logarithm ically with the web's size.

One of the prominent examples of a mathematical model of such a growing network is the scale-free (SF) construction of Barabasiand Albert [1,12]; and one of its m ost interesting properties is the very speci c form of the probability distribution of the degree of nodes (i.e. of the num bers of bonds connecting any given node iw ith other ones in the network): P (k) / k 3 [1,12{15]. M any m odels have been presented, based on the same two most important ingredients: growth and preferential attachment. Examples are models with an accelerated growth of the network [16,17], models with a nonlinear preferential attachm ent [15], with nodes provided by a initial attractiveness [13,18], with growth constraints as aging and cost [19,20], models that have a competitive aspect of the nodes [21], or models of networks that incorporate local events as the addition, rew iring or rem oval of nodes or edges [22].

The SF-construction m ay be a reasonable approxim ation for such world-spanning networks like one of the Intermet's inform ation transm ission channels or one of the form allinks of W W \cdot On the other hand, in m any sit-

uations (like in a network of hum an sexual contacts) a connection means a physical contact, i.e. means that the contacting individuals, representing the nodes of the network, have to occur at the same site and at the same time, thus introducing a clear geographical aspect. In what follows we present a simple model taking into account this metrical ("geographical") aspect, where the probability to connect two nodes depends both on the number of connections that the nodes already have (as in the genuine SF-construction), and on the distance between them . That is, we treat an emerging network in a m etric space. In this em erging network the probability that a new ly introduced node n is connected to a previously existing node i is proportional to the number ki of the already existing connections of node i (preferential attachm ent prescription), but on the other hand the too long bonds are disadvantaged, because this probability depends on the Euclidean distance din between the nodes n and i as d_{in} , (clearly, a "scale-free" function), with > 0.

Based on extensive numerical simulations of a onedim ensional situation, we show that even if the length penalties are mild, the model exhibits properties which dier strongly from those of the usual scale-free networks. Thus, the corresponding degree distribution function P(k) depends strongly on . We show, in particular, that for < 1 the behavior of P (k) is sim ilar to the behavior of the SF model without penalties, so that asymptotically P (k) / k^3 , (which distribution)possesses a mean, but no dispersion, and corresponds to strong, universal uctuations). On the other hand, for > 1 the behavior of P (k) is well-described by a stretched-exponential P(k) / exp(bk), with the power depending on , so that the uctuations in k are rather weak. We discuss the reasons for such a dram atic change, being rooted in the probability of connection between the nodes as function of the distance, and the overall structure of the em erging network, preserving its small-world nature even at large (probably at all) -values.

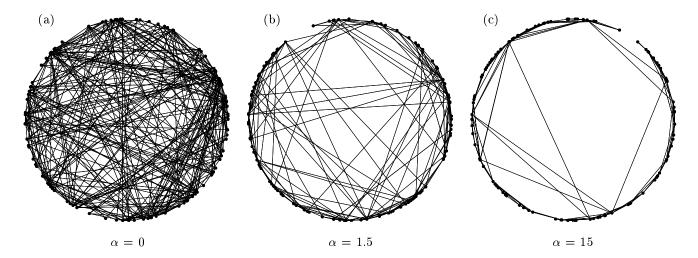

FIG. 1. Networks generated using the simulation prescription, Eq.(2), with dierent values of : (a) = 0, (b) = 1.5 and (c) = 15. All three examples have 300 edges, $L = 10^6$, N = 102, and m = 3. Note the change in the appearence of the networks. The network (a) is a genuine SF construction while (c) strongly resembles the W atts and Strogatz's small-world network.

We start from a one-dimensional lattice of L sites, spaced by a unit distance and apply cyclic boundary conditions. On this structure we will let our network grow, so that each lattice site will be a possible location of a network's node. We denote by \mathbf{n}_i the position in the lattice of a node i. The distance \mathbf{d}_{ij} between any two nodes i and j is de ned as:

$$d_{ij} = m \inf \dot{n}_i \quad n_j \dot{j} (L \quad \dot{n}_i \quad n_j \dot{j} g:$$
 (1)

Let us now construct the network. First, we choose random by an even number m $_{0}$ of sites from the lattice and we bind them in pairs with one bond each. This will be our initial condition. That is, at t = 0, our network will consist from m_0 nodes connected in pairs. As in the SF model we will add at every time step a new node to our network (linear growth). We proceed according to the following rule: at every time step we choose at random a free site of our lattice, and pose the new node there. This new node is then connected through m edges m₀) with m di erent nodes already present in the network. After t time steps the algorithm results in a network with t+ m $_0$ nodes and m t+ m $_0$ =2 edges. In contrast with the SF model, the probability for the new node n to be connected to an old one iwill depends not only on the number of edges ki which ialready possesses, but also on the distance d_{in} between them :

$$(k_{i};d_{in};) = \frac{p k_{i} d_{in}}{j k_{j} d_{in}}:$$
 (2)

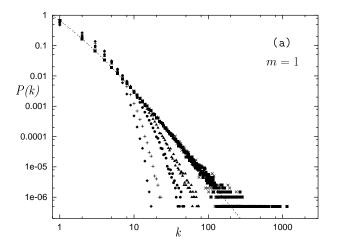

Here the sum in the denominator goes over all nodes in the system except the newly introduced one and is a real non-negative parameter describing the distance penalties. For large , the probability of connection between two distant nodes is very small. On the other hand, for a very small the probability is almost independent from the distance. In the case = 0 our model reduces to the genuine scale-free one. Note that our model is to some extent also scale-free: the connection probabilities depend only on the relative distances.

Our initial condition is slightly di erent from one of B arabasi and A lbert, where the initial m $_0$ nodes are not connected: in our case all nodes introduced at t = 0 have exactly one edge, which allows to use Eq.(2) from the very beginning. This simplies the algorithm, since we do not have to distinguish between the initial and the further steps. The only dierence with the genuine SF construction is that at time tone has mt+ m $_0$ =2 (instead of mt) edges present; hence, the asymptotic behavior of both models for t! 1 is the same.

Three exam ples of the evolving networks of such a kind are given en Fig.1. Here is m = 3, L = 10^6 , N = 102 and m $_0$ = 6, (so that all three networks have exactly 300 edges). Three di erent values of were used: = 0.0 (scale-free model), = 1.5 and = 15.0. Note that increasing leads to marked changes in the topology of the network. Fig. 1(a) corresponds to a genuine scale-free construction and exhibits a lot of long bonds connecting distance sites. On the other hand, only few such bonds are present in Fig. 1(c).

In our further simulations we use a lattice of L=2 10 sites; the maximal number of the introduced nodes is N=2 10. All simulation results are based on the average of 10 realizations of this structure. The error bars on Figs. 3-5 correspond just to this ensemble average. The simulations are done for several values of and for two

values of m , the number of the outgoing bonds: m = 1 and m = 3; m $_{0}$ = 2m .

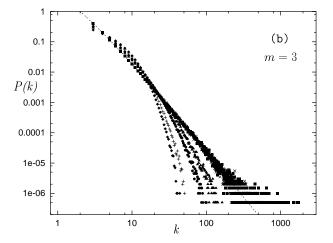

FIG. 2. The degree distribution P (k) for di erent values of and for m = 1 (a) and m = 3 (b). The values of are = 0 (squares), = 0.8 (crosses), = 1.5 (triangles), = 2 (lled circles), = 5 (plusses) and = 45 (diam onds). The dashed lines correspond to the theoretical curve for the scale-free m odel, (R ef. [1,12])

The distributions seem to be almost identical; however, small but statistically signicant deviations can be detected for small k-values. At '1 the degree distribution shows a pronounced change in its behavior and ceases being a power law; now the behavior of the model with distance penalties is quite dierent.

Let us concentrate on the case > 1 and try to describe the shape of the degree distribution under such conditions. The analysis of the simulations suggests that the corresponding mathematical expression could be a stretched-exponential function of the form:

$$P(k) = a \exp(bk);$$
 (3)

where the param eters a, b and depend on and m. To obtain the values of these param eter and to analyze the goodness of this tring function we have tred the data to Eq.(3) using the nonlinear least-squares Levenberg-Marquardt algorithm [23], taking into consideration the error bars as coming out of 10 realizations of each situation. The data is replotted together with the outcomes of the ts in Fig. 4 on the scales in which the tring function, Eq.(3), is represented by a straight line. One namely takes k as the abscissa and ln P (k) as the ordinata of the graph. Fig. 4 shows that such a t (straight line) is surprisingly good!

The values of the exponent are shown as a function of (>1) in Fig. 3, for the two dierent situations corresponding to m = 1 and m = 3. We see that monotonously grows with , and that the dependences m = 1 and m = 3 dier, i.e. that the () dependence is nonuniversal.

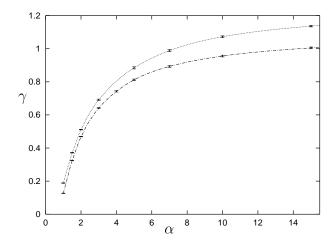

FIG.3. The parameter as a function of . The upper dependence corresponds to m=1, and the lower one m=3. The lines are drawn as a guide for eyes.

We note that in related models of growing networks another form of degree distribution appears: an exponentially demped power-law [24],

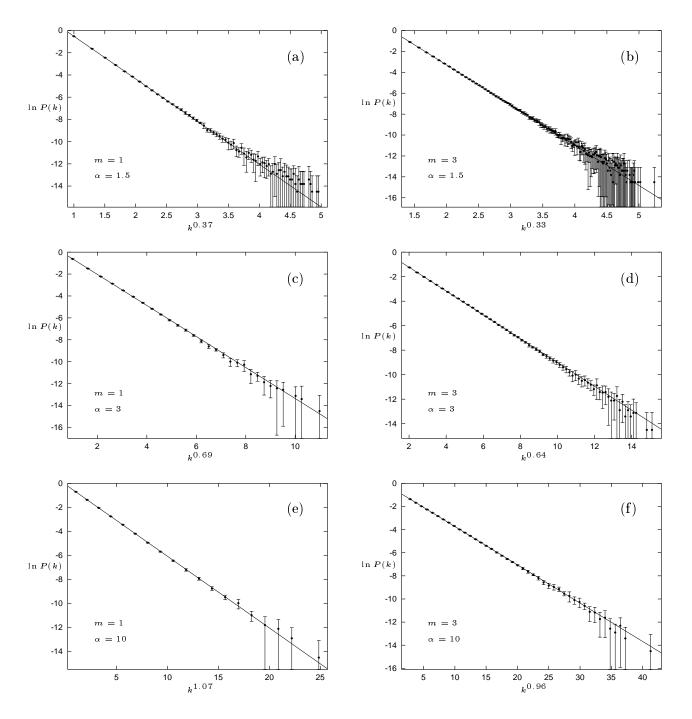

FIG .4. Shown is $\ln P$ (k) as a function of k , where is the output of the t, Eq.(3). (See text for details). The parameters are: (a): m = 1, = 1.5, = 0.37. (b): m = 3, = 1.5, = 0.33. (c): m = 1, = 3, = 0.69. (d): m = 3, = 3, = 0.64. (e): m = 1, = 10, = 1.07. (f): m = 3, = 10, = 0.96.

$$P(k) = ak exp(bk)$$
: (4)

We tested also this tfunction and found out that it gives a good tfor larger -values, but is de nitely inferior to our t, Eq.(3), for 1 < < 3.

A growing network with disadvantaged long bonds is a

very interesting hierarchical construction. Thus, for large , the strong correlation between the age of the connection and its length exists. The old connections, made when the nodes were sparce, are typically long, while the younger connections get shorter and shorter, since more sites in the immediate vicinity of a new ly introduced site

can be found. The simulations show that for large, the nodes are almost surely connected to their nearest neighbors. On the other hand, the old, long-range connections are of great importance for the overall topology of the lattice, since they guarantee that for any the network is a small-world one.

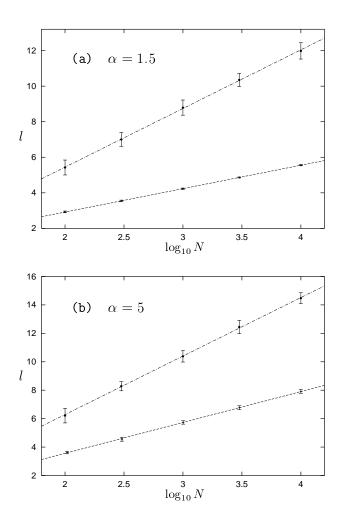

FIG. 5. The diameter of a network as a function of the number of sites N . Panel (a) corresponds to = 1.5 and panel (b) corresponds to = 5. The upper lines in each panel are those for m = 1, the lower lines correspond to m = 3. Note the logarithm is scale.

In Fig. 5 we plot the m ean number of connections between each two nodes of the network for two dierent values of (= 1.5 and = 5) and for the two values m = 1 and m = 3 as a function of the network size N . The algorithm here is trivial: starting from a node (labeled 0) we pass to all nodes connected to it (nodes of the rst generation, labeled 1), then to nodes of the second generation (labeled 2), etc; untill all nodes are labeled. The m ean distance between this node (labeled 0) and any other given node of the network is then the sum of all val-

ues of these labels divided by N 1. This procedure is repeated for each node, and the overall mean value, the so-called path diam eter of the network (1), is evaluated. The error bars of the gure correspond to the average of the mean diam eters over 10 realizations of the network. Fig.5 shows that the mean diam eter of the network grows linearly in $\ln N$, i.e. it shows the typical small-world behavior. This behavior is preserved for all tested values of ; the largest value tested was = 45; which, for m = 1, corresponds to a practically sure connection of a newly introduced node to its nearest neighbor. The high-networks resemble closely the simple small-world constructions [25].

Let us sum marize our ndings. We considered a growing network, whose growth algorithm is based, as in the SF construction, on a preferential attachment of the new ly introduced nodes to the highly connected old ones. However, here the too long connections are disadvantaged by introducing penalties. Thus, the probability to connect two nodes separated by a distance d is proportional to downwhere is a variable parameter. We found out that for <1 the degree distribution P(k) decays, as in the SF model, like P(k) k^3 , whereas for >1 a stretched exponential form P(k) = a exp(bk) gives an extremely good description of this distribution. On the other hand, the small-world property is preserved at all checked values of
