<sup>1</sup>Institute for Theoretical Physics, University of Heidelberg, Philosophenweg 19, D-69120 Heidelberg, Germany <sup>2</sup>Department of Physics, Temopil State Technical University, 56 Rus'ka Str., UA-46001 Temopil, Ukraine

(D ated: M ay 10, 2002)

W e present a stability analysis of the two-dimensionalt  $t^0$  H ubbard model for various values of the next-nearest-neighbor hopping  $t^0$ , and electron concentrations close to the Van H ove lling by means of the ow equation method. For  $t^0$   $t=3 \, a \, d_{x^2 \ y^2}$ -wave P omeranchuk instability dominates (apart from antiferrom agnetism at small  $t^0$ ). At  $t^0 < t=3$  the leading instabilities are a g-wave P omeranchuk instability and p-wave particle-hole instability in the triplet channel at temperatures T < 0.15t, and an s-m agnetic phase for T > 0.15t; upon increasing the electron concentration the triplet analog of the ux phase occurs at low temperatures. O ther weaker instabilities are found also.

PACS num bers: 71.10 Fd, 71.27.+ a, 74.20.-z, 74.20 Rp, 75.10.-b, 75.10 Lp

In recent years the two-dimensional (2D) H ubbard m odel has been used [1, 2] as the simplest m odel which m aps the electron correlations in the copper-oxide planes of high-tem perature superconductors since experimental data suggest that superconductivity in cuprates basically originates from the CuO<sub>2</sub> layers [3]. A lthough in the high-tem perature cuprate superconductors electron-electron interactions are strong some important features of these systems (in particular, antiferrom agnetic and d-wave superconducting instabilities) are captured already by the 2D H ubbard m odel at weak to m oderate C oulom b coupling.

A part from the antiferrom agnetism and  $d_{x^2 y^2}$ -wave superconductivity mentioned above (for review see [1, 2, 4] and references therein), a few other instabilities related to symmetry-broken states [5, 6, 7, 8, 9, 10, 11] in the 2D t  $t^0$  Hubbard model with next-nearest-neighbor hopping  $t^0$  have been reported recently. Specially, much interest of researchers has been attracted by the case when the Ferm i surface passes through the saddle points of the single particle dispersion (Van Hove lling). One of the instabilities found in such a case is a d-w ave Pom eranchuk instability breaking the tetragonal symmetry of the Ferm i surface, i.e. a spontaneous deform ation of the Ferm i surface reducing its symmetry to orthorhom bic. It has been recently observed for small values of  $t^0$  from renormalization group calculations by Halboth and M etzner [5]. They argued that the Pom eranchuk instability occurs more easily if the Ferm i surface is close to the saddle points with a sizable  $t^0$  (reducing nesting which leads to antiferrom agnetism). How ever, within their technique it is di cult to compare the strength of the Ferm i surface deform ation with other instabilities and to conclude which one dom inates. The authors of R ef. [10] have investigated the interplay of d-density wave [12, 13] and Ferm i surface deform ation tendencies with those tow ands d-w ave pairing and antiferrom agnetism by means of a sim ilar temperature— ow renorm alization group approach. They have found that the d-w ave P om eranchuk instability never dom inates in the 2D t  $t^0$  Hubbard model (even under the conditions mentioned above).

On the other hand, Vollhardt et al. [14] showed that the t<sup>0</sup>-hopping term destroys the antiferrom agnetic nesting instability at weak interactions in two and three dimensions, and supports the stabilization of metallic ferrom agnetism in in nite dimensions away from half-lling. Therefore, one could expect also the stabilization of ferrom agnetism by a sizable t $^0$  in two dimensions. Indeed, in the t  $t^0$  Hubbard model on a 2D square lattice at week to moderate C oulomb coupling, a projection quantum M onte C arlo calculation with 20 20 sites and the T-m atrix technique [6], a generalized random phase approximation including particle-particle scattering [7] point towards a ferrom agnetic ground state for large negative values of t<sup>0</sup>=t in a density range around the Van Hove lling. Sim ilar tendencies have been found by the authors of Ref. [8] within the renorm alization group and parquet approaches. Honerkamp and Salm hofer recently studied [9] the stability of this ferrom agnetic region at nite tem peratures by m eans of the tem perature- ow renorm alization group technique. They have found that ferrom agnetic instability is the leading one at t $^0<$ 0:33tand Van Hove lling with critical tem peratures depending on the value of t. When the electron concentration is increased slightly above the Van Hove lling, the ferrom agnetic tendencies get cut o at low tem peratures and a triplet p-wave superconducting phase dom inates. However, they did not consider the Pom eranchuk instability (which could have the m ost favorable conditions to occur) and other ones apart from antiferrom agnetism, d- and p-w ave superconductivity and ferrom agnetism .

Therefore, the investigation of interplay and rivalry between the Pom eranchuk instability and ferrom agnetism, and other phases in the 2D t  $t^0$  Hubbard model at the Van Hove lling is a considerable task. We will consider the leading instabilities depending on the ratio U=t (in all papers cited above it was xed). The main goal of this paper is such a study. We report also a few new instabilities in a range of electron concentration around the Van Hove lling.

W e start from the H am iltonian of the t  $t^0$  H ubbard m odel

$$H = \sum_{k}^{X} \mathbf{w}_{k} c_{k}^{Y} c_{k} + \frac{U}{N} \sum_{\substack{k_{1} k_{1}^{0} \\ k_{2} k_{2}^{0}}}^{X} c_{k_{1}}^{Y} \mathbf{w}_{k_{1}}^{0} c_{k_{2}}^{Y} \mathbf{w}_{k_{2}}^{0} \mathbf{w}_{k_{1} + k_{2} k_{1}^{0} + k_{2}^{0}}^{Y};$$
(1)

where " $_k$  is the B loch electron energy with the momentum  $k, c_k^{\gamma}$  ( $g_k$ ) is the creation (annihilation) operator for the electrons with spin projection 2 f"; #g, U is the local C oulom b repulsion of two electrons of opposite spins, N is the num ber of lattice points, lattice spacing equals unity.

By means of the ow equation method [15] the Ham iltonian is transformed into one of molecular-eld type. This Ham iltonian is calculated in second order in the coupling U [11]. A dopting the notations of Ref. [11], the expression for the free energy has the form :

$$F = \frac{1}{N} \sum_{kq}^{X} U + \frac{U}{t} V_{k,q} + \sum_{k=q}^{X} f_{k-k-k};$$
(2)

where the st term is the energy contribution and the second term is the entropy contribution,  $= 1 = (k_{\rm g} T)$ , T is the temperature, t is the hopping integral of electrons between nearest neighbors of the lattice,  $V_{k;q}$  is electrive second-order interaction (the factor U<sup>2</sup>=t has been extracted from it),  $f_{k}$  is an entropy coeccient, and k are the order parameters. For example,  $k; k \circ = h_k c_k \circ i = (y) \circ \sum_{k}^{s} + (y) \circ \sum_{k}^{t}$ , where is a Pauli spin matrix (= x; y; z), and  $\sum_{k}^{s} (\sum_{k}^{t})$  is the singlet (triplet) amplitude. An expression similar to Eq. (2) is obtained for particle-hole channels with the order parameters instead of . In this case, for example, we have  $k; k \circ = h_k^{Y} c_{k+Q} \circ i = \sum_{k}^{s} \cdot \circ + \sum_{k}^{t} () \circ w$  ith Q = (;). All quantities of Eq. (2) are de ned in Ref. [11]. For a square lattice the single particle dispersion has the form :

$$\mathbf{w}_{k} = 2t(\cos k_{x} + \cos k_{y}) \quad 4t^{0} \cos k_{x} \cos k_{y} : \tag{3}$$

The spectrum (3) contains Van Hove singularities in the density of states at the energy  $"_{VH} = 4t^0$  related to the saddle points of the Ferm i surface at k = (0; ) and (; 0). For  $t^0 = 0$  and half-lling the Ferm i surface is nested " $_{k+Q} = "_k$ , which leads to an antiferrom agnetic instability for U > 0. The nesting is removed for  $t^0 = t \in 0$ .

We start from the symmetric state and investigate whether this state is stable against uctuations of the order parameters and . As soon as a non-zero or yields a lower free energy in comparison with the symmetric state with all vanishing and , then the symmetric state is unstable and the system will approach a symmetry broken state. This indicates a phase transition.

We perform numerical calculation on a square lattice with 24 24 points in the Brillouin zone for the various representations under the point group  $C_4$ . The representations of the even-parity states are one-dimensional. We denote them by  $s_+ = s_1$ ;  $s_- = s_{xy(x^2-y^2)}$ ;  $d_+ = d_{x^2-y^2}$ ;  $d_- = d_{xy}$ . The odd-parity representation is two-dimensional, here simply denoted by p. Initially, such numerical calculations have been performed in Refs. [11, 16], but they were sensitive to the lattice size at low temperatures. Here we use an improved scheme (for details see Ref. [17]).

We start from  $t^0 = 0$  and half- lling (n = 1) (see Fig. 1). As expected in this case the leading instability is the antiferrom agnetic one which disappears at the temperature T 0:1t or doping n = 1 = 0.06. The next instability is a Pom eranchuk instability with  $d_{x^2 - y^2} - w$  ave symmetry in the singlet channel. The corresponding eigenvectors signals a deformation of the Ferm is urface which breaks the point group symmetry of the square lattice. For negative  $t^0 = t=3$  the Pom eranchuk instability dom inates at the Van Hove lling (see Fig. 2). The  $d_{x^2 - y^2} - w$  ave Pom eranchuk instability competes with other instabilities at  $t^0 < t=3$ , and it is not the leading one (Fig. 3). In agreement with the ideas of R ef. [5] the instability is mainly driven by a strong attractive interaction between particles on opposite corners of the Ferm i surface near the saddle points and a repulsive interaction between particles on neighboring corners. To favor such a behavior we need a sizable  $t^0$  reducing antiferrom agnetic correlations.

At half- lling and  $\ell = 0$  the next instability is a particle-hole instability of singlet type with staggered p-wave symmetry. It yields [11] a splitting into two bands and may lead to an energy gap in the charge excitations spectrum. A notherm echanism for a charge gap formation has been proposed [18, 19] recently in the 2D Hubbard model with  $t^0 = 0$  at weak coupling. The band splitting phase is developed in the region of electron concentration around half-lling, and is one of the strongest in that region. Then the superconducting  $d_{x^2 \ y^2}$  instability follows which coincides with the  $d_{x^2 \ y^2}$ -wave staggered ux phase (the ux phase has been proposed by the authors of R ef. [20, 21] and discussed recently in R efs. [12, 13, 22]). A way from half-lling the degeneration disappears, and d-wave superconductivity dom inates at low temperatures in certain regions of electron concentration around half-lling which depends on the value of  $t^0 \notin 0$ . Even large values of  $j_*^0$  do not destroy the dom inant low-temperature behavior of  $d_{x^2 \ y^2}$ -wave superconductivity at doping [17]. O ne phase may suppress another phase. To which extend two order parameters can coexist with each other is a question, which has to be investigated in the future.

For  $t^0 = 0$  the singlet and triplet  $T_c$  of the particle-hole instabilities with staggered symmetry of d, wave character (that is the ux phase) are degenerate. If  $t \in 0$  they are dimensional error, and the triplet one is higher. Moreover, the triplet analog of ux phase dominates at low temperatures and t = 5t=12 when the electron concentration is slightly above the Van Hove lling (see Fig. 4) in contrast to the results of Ref. [9] which point out the occurrence of triplet superconductivity with p-wave symmetry in this region. The triplet ux phase is also one of the leading instabilities for  $t^0$  t=3 and certain region of electron concentrations (see Fig. 2). It has been considered by N ayak [12] as a density wave order parameter potentially relevant to the cuprates, but to our know ledge a triplet version of the ux phase has not yet been observed in numerical solutions of the 2D t  $t^0$  Hubbard model. We shall discuss this state in more details elsewhere [17].

At  $t^0 = 5t=12$  a few other new instabilities appear to compete at the Van Hove lling and low temperatures (Fig. 3) in disagreement with the conclusions of Ref. [9] on the occurrence of ferror agnetism. The leading one is a Pomeranchuk instability in the s<sub>+</sub> channel with  $g_t = g_{x^4+y^4-6x^2y^2}$  wave character (4 node lines in k-space). This phase occurs more easily if the electron concentration is close to or slightly smaller than the Van Hove lling (Fig. 5). It requests also su ciently large absolute values of  $t^0$ . When the electron concentration is decreased below the Van Hove density, a particle-hole instability of p-wave symmetry in triplet channel an i-wave (6 node lines in k-space) Pomeranchuk instability appears when electron concentration n is smaller or close to the Van Hove lling (Figs. 3-5). It is a leading one at small values of the electron concentration [17]. We observe (Fig. 5) in the s<sub>+</sub> channel a g<sub>+</sub> wave superconductivity below the Van Hove lling, but it requires strong coupling.

A nother situation occurs at the tem perature region T > 0.15t. Here a particle-hole instability with s -wave character (its order parameter changes sign close to the Ferm i-edge) in the triplet channel dom inates at the density range around the Van Hove lling (see Figs. 3-5). It is likely that the order parameter contributions do not compensate exactly, so that a weak ferrom agnetism appears. When the electron concentration is increased above the Van Hove lling this instability does not become weaker, but the  $d_{x^2 y^2}$  wave Pomeranchuk and the triplet ux phase instabilities are manifested stronger (they dom inate at low tem peratures). Then, this s -m agnetic phase disappears at su ciently large values of electron concentration in comparison with the Van Hove lling, or sm aller fj.

From Figs. 3-5 one can see a reentrant behavior of the s-m agnetic phase in some region of the values U=t: approaching  $T_c$  we get  $T_c^1$  from low temperatures and  $T_c^u$  from high temperatures at the same value of coupling U=t  $(T_c^1 \in T_c^u)$ . This is a result of di erent behavior of  $T_c(U=t)$  in two regimes. First regime occurs in the situation where the s-m agnetic instability dom inates and the transition from a param agnetic state to the s-m agnetic phase occurs directly without any intermediate phase, it corresponds to the temperatures T > 0.15t on Figs. 3, 5. In this case the critical temperature increases with the increase of correlation strength U=t. Another regime occurs at the temperatures T < 0.15t. In this situation the critical temperature exhibits an anom alous behavior, it decreases with increasing the coupling U=t. The s-m agnetic phase is reduced. Since at lower temperatures only a sm aller region in k-space around the Fermi-edge contributes, the sign-change of the order param eter reduces the expectation.

In conclusion, we have presented a stability analysis of the 2D t t<sup>0</sup> Hubbard model on a square lattice for various values of the next-nearest-neighbor hopping t<sup>0</sup> and electron concentrations close to the Van Hove lling. A surprising large number of phases has been observed. Some of them have an order parameter with m any nodes in k-space. For t<sup>0</sup> t=3 the d<sub>x<sup>2</sup> y<sup>2</sup></sub>-wave Pom eranchuk instability dom inates. At t<sup>0</sup> < t=3 the leading instabilities are a g<sub>+</sub> wave Pom eranchuk instability and p-wave particle-hole instability in triplet channel at temperatures T < 0:15t, and s -m agnetic phase for T > 0:15t; upon increasing the electron concentration the triplet ux phase occurs at low temperatures. The s -m agnetic phase is reduced strongly at low temperatures. We have found other weaker instabilities also.
