A compact expression has been obtained for the superexchange coupling of magnetic ions via intermediate anions with regard to polaron effects at both magnetic ions and intermediate anions. This expression is used to analyze the main features of the behavior of isotope shifts for temperatures of three types in layered cuprates: the Neel temperatures (T_N), critical temperatures of transitions to a superconducting state (T_C), and characteristic temperatures of the pseudogap in the normal state (T).

74.25.-q, 74.72.-h

Elucidating the nature of unusual isotope effect in copper-oxygen superconductors is one of the most important problems on the way to ascertaining the mechanism of the pairing of charge carriers in these compounds. It is known that the observation of an isotope shift of the superconducting transition temperature (T_C) was of crucial importance in ascertaining the phonon mechanism of pairing in conventional (low-temperature) superconductors. The fact that an isotope effect exists in high-temperature superconductors built up of copperoxygen planes has long been beyond question; however, the relative smallness of the coefficient (for example, 0.056 for $\text{YBa}_2\text{Cu}_4\text{O}_8$ upon replacing ^{16}O with ^{18}O , instead of the standard value 0.5) and the specific features of its behavior in other compounds upon changing the number of holes in copper-oxygen planes do not fit the Bardeen-Cooper-Schrieffer (BCS) scenario. At the same time, the majority of authors of articles related to the isotope effect (see the recent review [1]) correctly point out that, nevertheless, phonon modes, in some mysterious way, affect the superconducting transition temperature. In this context, we believe that the facts of observing an isotope effect for the characteristic temperature of the pseudogap state of underdoped cuprates (so-called pseudogap onset temperature T) gain great importance. Thus, according to [2], the isotope exponent upon replacing ^{16}O with ^{18}O corresponding to T is $\alpha = 0.061$. It was natural that this fact suggested a common origin of T_C and T [2].

We believe that another and even more important similarity in the dependence of the order parameters of the superconducting and pseudogap phases on the d -type wave vector (that is, $\cos q_x$ vs $\cos q_y$) was explained in its time under the assumption that the transitions to both these phases are associated with short-range potentials [3]. It seems that superexchange interaction, screened

Coulomb repulsion, and interaction of holes mediated by optical phonons are the most significant of these. The isotope shift of T_C and T due to interaction mediated by optical phonons was discussed in a few works (see, for example [4,5]), and that for T was considered in [6]. Below, we will focus our attention on polaron corrections to the superexchange coupling of copper spins (J) and will demonstrate that a number of features in the behavior of the isotope shift of T_C upon changing the number of holes in the CuO_2 plane can be quite reasonably explained even within the framework of the purely superexchange mechanism of pairing. First, we emphasize the following important fact. Within the scenario [3], the superconducting transition temperature $T_C = 2J/G$, whereas the characteristic temperature of the pseudogap phase $T = J + G$ [3,7]. Here, G is the parameter of the screened Coulomb interaction of holes on the nearest copper sites, which partially includes the correction due to interaction mediated by optical phonon modes. If it is granted that the isotope shift is associated with the phonon renormalization of G , the shifts of T_C and T would be of opposite sign, which is in contradiction with the experimental results [2]. In this connection, it is believed that the scenario of phonon renormalization of the parameter J is more reasonable to suggest as the source of positive isotope shifts of T_C and T .

The renormalization of J within the Hubbard model was investigated in detail by Kugel and Khomskii [8]. It is evident from the above estimates $T_C = 2J/G$ and $T = J + G$ that the small increase in J proportional to the phonon frequency found in this work gives the correct sign of isotope shifts but does not provide the required magnitude of the shifts. This can be most simply demonstrated with the example of the isotope shift of the Neel temperature in related high- T_C compounds. As was already indicated in [1], the Kugel and Khomskii's correction gives a correct sign of the isotope shift of the Neel temperature (T_N) in La_2CuO_4 upon replacing ^{16}O with ^{18}O ; however, even the most overrated estimates give a value that is six times lower than the experimental one.

We believe that the main reason for the quantitative disagreement between the theory [8] and the experiment [1] is in the fact that the Hubbard model is not suitable for the compounds of our interest. As was already stressed in [9], that the energies of electron transfer from oxygen to a magnetic ion (ϵ_c) in the majority of copper oxides are smaller than the energy of electron transfer from copper to copper (ϵ_a). However, the Hubbard

model gives correct estimates only when $a \ll c$.

The Hamiltonian in the form

$$\hat{H} = \sum_a U_a n_a^\uparrow n_a^\downarrow + \sum_c U_c n_c^\uparrow n_c^\downarrow + \sum_{\langle a,b \rangle} t_{ab} c_a^\dagger c_b + c_a^\dagger a : \quad (1)$$

is best suited to the description of superexchange interaction with taking into account explicitly the cascade hopping of electrons over oxygen. As applied to high- T_c superconductors, it is rather frequently named the Emery Hamiltonian. Here, t_{ac} is the hopping integral between neighboring copper and oxygen sites, and U_a and U_c are the parameters of electron Coulomb repulsion. We will estimate the corrections to the superexchange parameter J due to polaron effects at copper (a) and oxygen (c) sites in the fashion of [8], supplementing Eq. (1) with the electron-phonon coupling operator

$$\hat{H}_{ep} = \sum_{a,b;c} g_i n_i p_q + p_q^\dagger : \quad (2)$$

Here, p_q and p_q^\dagger are phonon annihilation and creation operators, and g_i is the coupling parameter connected with the polaron stabilization energy (E_i) at site i by the equation $E_i = g_i^2 / \hbar \omega_i$, where ω_i are local vibrational frequencies.

In the physical context, this calculation corresponds to a simplified Holstein model when the migrating charge locally interact with breathing modes, forming electron-vibrational states with dispersionless optical phonons. In this connection, it is pertinent to note that conduction in the compounds under consideration is just of the polaron type and is accomplished mainly via oxygen ion sites [10].

This calculation is most simply performed by the method of canonical transformations. The matrix of the unitary transformation of the initial Hamiltonian is found by excluding the odd terms with respect to hopping integrals with an accuracy of to sixth-order perturbation theory. The calculation, whose mathematical details will be given in a more detailed article, gives the following result:

$$J = J_0 \left(1 + \frac{3\hbar}{(c_a)^2} E_a \omega_a \coth \frac{\hbar \omega_a}{2k_B T} + \frac{E_c \omega_c \coth \frac{\hbar \omega_c}{2k_B T}}{E_a \omega_a} \right) ; \quad (3)$$

where $t_{ac} = t_a t_c + U_a U_c$ has the meaning of the energy of transfer from oxygen to copper, and the corrections proportional to $E_a \hbar \omega_a = t_{ac} U_a^2$ and $E_a \hbar \omega_a = U_a^3$ are not given because of their smallness for the compounds under consideration. J_0 is the parameter of superexchange interaction of copper spins via the intermediate oxygen atom in the absence of phonons [9,11]. Note that the appearance of temperature factors in our equation is

generally characteristic for the problems on transitions in transition metal compounds with the participation of quasilocal vibrations [12]. At the same time, one should keep in mind that polaron effects break down at $T \rightarrow 0$, and the concepts used here become inapplicable.

The results of our calculation are given in the figure. The system of integral equations for the mean field parameters corresponding to the transition to the pseudogap phase was solved self-consistently. We identify the pseudogap phase with the phase of sliding charge-density waves. This system was written in detail in [3] and is not given here.

For the description of the superexchange coupling parameter upon replacing some isotopes for other ones at $\hbar \omega \approx k_B T$, it is convenient to introduce parameters ω_{Cu} and ω_O by writing

$$J = J_0 \left(1 + \omega_{Cu} \frac{M_{Cu}}{M_O} + \omega_O \frac{M_O}{M_{Cu}} \right) : \quad (4)$$

It follows from Eq. (3) that, upon replacing ^{16}O with ^{18}O ,

$$\omega_O = \frac{3}{2} \frac{E_a \hbar \omega_a}{\omega_{Cu} \omega_O} ; \quad (5)$$

whereas, upon replacing ^{63}Cu with ^{65}Cu ,

$$\omega_{Cu} = \frac{3}{2} \frac{E_c \hbar \omega_c}{\omega_{Cu} \omega_O} : \quad (6)$$

Substituting here (in electronvolts) $\omega_{Cu} \omega_O = 1.5$ [13] and standard values $\hbar \omega_a = 0.05$, $E_a = 0.4$ [10,14], and using the relationship $T_N = T_N^0 J = J$ characteristic for layered cuprates (see [1]), we find that the Neel temperature should decrease by 0.2% upon replacing ^{16}O with ^{18}O in $YBa_2Cu_3O_{6.383}$. According to measurements in La_2CuO_4 [15], the shift $\Delta T_N = 0.6\%$. If, however, it is assumed, following [1], that $E_a = 1.2$ eV, our estimate will coincide with the experimental value. We hope that this explanation of the isotope shift of T_N will stimulate further experimental investigations of this important problem. Our estimated value $\omega_O = 0.014$ is overrated. The value $\omega_O = 0.01$ is better suited to comparison of the calculated with experiment, see the figure.

It is pertinent to note that, generally speaking, there is another possibility of changing J given by Eq. (4). This possibility is associated with the change in the distance between copper ions upon replacing some isotopes with other ones. It is known that the superexchange parameters very strongly depend on the distance between the interacting ions. This mechanism explains well the increase in T_c under the action of an external pressure on a high- T_c crystal [16,17]. The question naturally arises in this case of what occurs with the lattice parameters upon changing some isotopes for other ones. Recent precise measurements in $YBa_2Cu_4O_8$ crystal showed [18]

that the lattice parameters a , b , and c in the case of ^{16}O equal (in Å) 3.8411 (1), 3.8717 (1), and 27.2372 (8), respectively, whereas these are equal to 3.8408 (1), 3.8718 (1), and 27.2366 (8), respectively, for ^{18}O , that is, these parameters are somewhat smaller in the latter case. The positive isotope shift of the nuclear quadrupole resonance frequency of plane copper nuclei [18] is another important experimental fact, which indicates that interatomic copper-oxygen distances are smaller in the case of ^{18}O . Based on these data, one may only conclude that the change of interatomic distances upon replacing some isotopes with other ones must lead to negative shifts of T_c and T^* and will, probably, be relatively small. From the theoretical point of view, this fact seems quite understandable, because changes in interatomic distances upon replacing some isotopes with other ones are due to the lattice anharmonicity, and its effect is naturally of less importance than the effect of harmonic vibrations.

FIG. 1. The calculated exponent of the isotope shift of T_c upon replacing ^{16}O with ^{18}O as a function of the number of holes per one copper site.

In the figure, the values of the coefficient $T_c = d \ln(T_c) / d \ln(M)$ for the replacement of ^{16}O with ^{18}O are plotted as abscissas, and the numbers of holes per one copper site are plotted as ordinates. The symbols in the curve correspond to the points at which the system of self-consistent equations from [3] was solved. Because only the order of magnitude is known for the polaron energies E_a and E_c , the parameter γ_0 was normalized in such a way that T_c was equal to 0.1 at the optimal level of doping. The calculated behavior of T_c is not symmetric with respect to the point of optimal doping. The physical nature of this asymmetry is associated with strong competition between d-SC and id-CDW phases in the underdoped state. On the left of this point, the isotope shift exponent increases with decreasing number of holes, approaching 0.5, whereas the value of T_c remains virtually constant as well as it does at $\delta/2$ greater than 0.16 (so-called overdoped regime). This kind of asymmetry (but without a step!) in the behavior of T_c as

a function of the number of holes was found recently in measurements [19]. The authors of this work mentioned already that, if only conventional interaction via the phonon field were responsible for the isotope effect and the unusual drop in the optimal doping region were related to a peak in the density of states, the curve would be approximately symmetric with respect to the point of optimal doping. At $\delta/2$ larger than 0.16, the value of T_c would strongly increase; however, this was not found [19].

As to the isotope shift of T_c upon replacing the copper ^{63}Cu isotope with ^{65}Cu or ^{66}Cu , the fact noted in [20] that the ratio $T_c(\text{Cu}) / T_c(\text{O}) = 0.75 \pm 0.1$ does not depend on the type of the compound and on the doping level is naturally explained based on Eq. (3). The stabilization energy of a small-radius polaron (hole) at a copper site is higher than that at an oxygen site. The nearest environment of a hole at an oxygen site comprises positive copper ions, whereas the nearest environment of copper comprises negative oxygen ions. This fact is the reason for the difference between γ_o and γ_{cu} .

The value of T_c calculated in this work in the region $0.1 < \delta/2 < 0.16$ turned out to be approximately constant: $T_c \approx 0.01$. This is smaller than the value estimated in experiments (0.061) [2]; therefore, the effect of interaction via optical phonons on T_c discussed in [2] cannot be excluded. This is also corroborated by a number of experimental points in Fig. 2 from [19] on the right of the point of optimal doping. We hope to describe this problem in a more detailed work.

Thus, the renormalization of the superexchange interaction of copper spins due to polaron effects noted in this work explains the main regularities of the isotope shift of the superconducting transition temperature in layered cuprates both in the order of magnitude and in the sign and the character of the dependence on the number of holes. The starting equation for the renormalization of the superexchange parameter was verified using the isotope shifts of the Neel temperature of the parent compounds as an example. Our calculations were based on the scenario of competition between the superconducting phase and the charge-density-wave phase. Agreement between the calculations and experiment confirms this scenario. At the same time, our calculation predicts a rather sharp jump of the isotope exponent T_c on passing through the point of optimal doping. This effect is relatively small; however, we believe that the experimental observation of this effect would be of principal importance.
