(Dated: April 14, 2024)

W e explore the use of exact diagonalization m ethods for solving the self consistent equations of the cellular dynam ical m ean eld theory (CDMFT) for the one dimensional regular and extended H ubbard m odels. W e investigate the nature of the M ott transition and convergence of the m ethod as a function of cluster size as well as the optim al allocation of com putational resources between bath and \cluster-im purity" sites, w ith a view to develop a renorm alization group m ethod in higher dimensions. W e assess the perform ance of the m ethod by com paring results for the G reen's functions in both the spin density wave (SDW) and charge density wave (CDW) phases w ith accurate density m atrix renorm alization group (DMRG) calculations.

#### I. IN TRODUCTION

The dynamical mean eld theory (DMFT) has been successful in accessing certain aspects of the nonperturbative phenom ena in strongly correlated electron system s. For example, it has given new insights and predicted various qualitative trends in the redistribution of spectral weight as tem perature, pressure and doping are varied in optical and photom ission experiments, near the M ott transition.

Single site DMFT extracts physical quantities such as the self energy from a local impurity model with a self consistent bath (also referred to as LISA for local impurity self consistent approximation) and by construction this approach misses the e ects of short range correlations, such as the k-dependence of the self energy, which are bound to become important at low temperatures. It also does not allow the treatment of phases such as d-wave superconductivity, and hence there have been signing cant e orts to extend the DMFT methodology<sup>1,2,3,4,5,6,7,8</sup>.

Many of the elements of the DMFT method can be traced back to the coherent potential approximation (CPA)<sup>9</sup> which has been very successful in disordered systems. In this context, the search for extensions of the CPA was fraught with many di culties, and extensions of DMFT should be scrutinized carefully in this light. The DMFT equations, while having a similar spirit to those of CPA for determ ining the e ective medium, are considerably m ore com plex because they involve the solution of a quantum im purity model, which plays the role of the e crive H am iltonian for the local degrees of freedom treated in the DMFT. To analyse these equations new concepts and num erous techniques have been developed over the last decade. Their incorporation into cluster m ethods is prom ising but requires substantial new work. This paper is a contribution in this direction. In this paper we focus on one cluster extension of DMFT, the Cellular Dynamical Mean Field Theory (CDMFT)<sup>5,10</sup>. The aim of this paper is to investigate how the exact diagonalization aproach which was so successful in the context of the single site DMFT<sup>11,12,13</sup>, can be used in

#### the CDMFT context.

We solve the self consistent cluster equations for the one dimensional Hubbard and extended Hubbard models using exact diagonalization of the elective underlying cluster impurity. We choose these models because of their generic nature, as well as the fact that DMFT, which becomes exact in the limit of in nite coordination number<sup>14</sup>, faces the worst case scenario in one dimension. Furthermore in one dimension fairly reliable computations of static as well as dynam ic quantities can be made using the Density Matrix Renormalization G roup (DMRG)<sup>15,16,17</sup> approach to carry out a comparative study.

The exact diagonalization approach, within the single site DM FT context, lead to the development of a technique inspired by renormalization group ideas which resulted in the st quantitative study of the critical properties near the M ott transition<sup>18</sup>. W ith a view towards the future, we discuss the possibility of combining renormalization group ideas and CDM FT to develop a new num ericalmethod in the spirit of the DM RG.

The Extended Hubbard Model (EHM) is de ned by the following Hamiltonian:

$$H = t c_{j+1}^{y} c_{j} + h c + U n_{j''} n_{j\#}$$

$$K + V n_{j} n_{j+1} n_{j} (1)$$

$$j j j$$

The rst term corresponding to hopping between nearest neighbor sites and the second term to the onsite C oulom b repulsion provide the competition between itineracy and localization in the regular H ubbard m odel. The third term represents C oulom b repulsion between electrons occupying nearest neighbor sites. The H am iltonian as written above with = U=2 + 2V guarantees an insulating ground state with a lling of one electron per site.

In the following section we introduce and discuss the CDMFT self consistency equations and show how they can be generalized to treat non-local Coulomb interactions even in the presence of broken symmetries. In the next and subsequent sections we present results for the regular Hubbard and the extended Hubbard model respectively. This is followed by the conclusions and an outlook for further work.

## II. THE CDMFT METHOD

The CDMFT<sup>5</sup> method is a straightforward generalization of the single site DMFT, in which local degrees of freedom within a cluster are treated exactly and those outside the cluster are replaced by a bath of noninteracting electrons determ ined self consistently. This approach, form ulated with realistic studies in mind, deals in principle with overlapping cells and with clusters which are not necessarily de ned in real space and could even be de ned by non-orthogonal orbitals. In this paper, we ignore these complications and work with real space clusters using an orthogonal basis. It is worth pointing out, that if we apply the approach to non-interacting disordered alloys, the self consistency condition of CDMFT becom es identical to that used in the molecular CPA approximation of Ducastelle<sup>19</sup>. This is in the same way as the self consistency condition in single site DMFT becom es identical to the single site CPA and the two im purity approximation proposed by Ingersent and Schiller<sup>20</sup> and by Georges and Kotliar<sup>1</sup>, becomes identical to the pair CPA. How ever, unlike the single site case, where the transition from real space to momentum space is unam biguous, one has to be careful in interpreting the results of the CDMFT equations in k-space. This is because the goal of CDMFT is to obtain the best possible estimates of local quantities that live within a cluster. For this purpose, it introduces a cluster self energy. Long distance properties such as the ones contained in the lattice G reen's function and the lattice self energy are then inferred from the cluster G reen's function or the cluster self energy while maintaining causality<sup>5</sup>.

## A. The Cavity Construction

The most economical way to arrive at the concepts of a dynamical mean ekd theory is via the cavity construction, which stresses the point made above, that the focus of the method is in extracting local quantities. The original lattice is divided into equal clusters of size N $_{\rm c}$ . Integrating out the degrees of freedom external to a chosen cluster (labelled 0), we can form ally write an elective action which would allow the computation of local quantities as

$$\frac{1}{Z_{e}} e^{S_{eff} [c_{0}^{y}, c_{0}]} \frac{1}{Z} \begin{bmatrix} Z & Y \\ & D & C_{j}^{y} & D & c_{j} & e^{S} \\ & & & & j \neq 0; \end{bmatrix} (2)$$

Here j labels individual clusters and is an index labelling sites within each cluster. We can split the original action into three parts,

$$S = S^{(0)} + S_0 + S;$$
(3)

where S  $^{(0)}$  includes term s outside the chosen cluster (the full action with the cluster replaced by a cavity), S<sub>0</sub> com – prises of terms solely within the cluster and nally, S includes those terms that couple the cluster with its environment. Explicitly, in the case of the EHM,

$$S_{0} = \begin{array}{ccccc} Z & X \\ S_{0} = & d & C_{0}^{V} & ( & Q + E^{00}, )c_{0} \\ & & , & X \\ & & X & X \\ & + & U n_{0} * n_{0} # + V & n_{0} n_{0} & (4) \end{array}$$

Here  $\hat{E}^{00}$  includes the hopping matrix as well as the chem icalpotential within the zeroeth cluster and hj; 0 i denotes all intercluster nearest neighbors. It is to be noted that, while the onsite C oulom b interaction U contributes only to  $S_0$ , a nonlocal interaction such as the nearest neighbor Coulomb repulsion V contributes to both S<sub>0</sub> as well as S. This cavity construction is so far m erely a relabelling of terms in the original action and is exact. However approximations need to be made to actually access the local properties within the cluster. We approxim ate the e ective action of the cluster by keeping only the renorm alization of the quadratic term s obtained after integrating out the degrees of freedom of the surrounding environm ent<sup>1</sup>. Notice that this approxim ation violates the translational sym m etry of the original lattice. But this is not a problem, since the spirit of the approach is to estim ate local quantities. The G aussian approxim ation for the e ects of the environm ent seen by the cluster becomes exact in the limit of large coordination<sup>1</sup> and therefore, our test case in one dimension constitutes the worst case scenario. The e ective action for the cluster can then be approxim ated as,

Here, the time dependent W eiss  $eld\hat{G}_0^{-1}$  is now a matrix in the cluster variables and is a functional of the EHM G reen's function with the cluster replaced by a cavity. Suppressing spin indices, it can be written on the M atsubara axis as

Relating the cavity G reen's function, G  $^{(0)}$ , to the full G reen's function of the EHM, the following self consistency condition to determ ine the W eiss eld can be obtained:

$$\hat{G}_{0}^{1}(\underline{i!}_{n}) = \hat{G}_{loc}^{1}(\underline{i!}_{n}) + \hat{C}_{c}(\underline{i!}_{n}); \quad (7)$$

where the local G reen's function on the cluster in one dimension is de ned as (with an obvious generalization to higher dimensions)

$$\hat{G}_{loc}(\underline{i!}_{n}) = \frac{1}{\sum_{n=N_{c}}^{N_{c}}} \frac{1}{\underline{i!}_{n} + \widehat{C}(\underline{i!}_{n}) + \widehat{C}(\underline{k})} \frac{dk}{2 - N_{c}}:$$
(8)

 $\hat{c}_{c}$  is the cluster self energy as obtained from  $S_{e}$ ,  $\hat{t}(k)$  is the Fourier transform of the cluster hopping matrix of the EHM and k is a vector in the reduced B rillouin zone of the superlattice ( $\frac{1}{N_{c}}; \frac{1}{N_{c}}$ ]. Explicitly for a one dimensional model with only nearest neighbor hopping,

$$t (k) = t[ _{1} + e^{ikN_{c}} _{N_{c}+} _{1} + e^{ikN_{c}} _{N_{c}+} _{1}]$$
(9)

### B. A functional interpretation

A second approach to derive the above approximation is via the construction of a functional of the quantities of interest, say the G reen's function restricted to a local cluster and its supercell translations, such that the stationary point of the functional yields those quantities<sup>21</sup>. In principle such a functional can be constructed order by order in a perturbative expansion in the hopping or the interactions while constraining the G reen's function to a xed value. In practice, sensible approximations to the exact functional are contructed by starting with the full Baym-Kadano functional [G] and restricting its argument from the full G reen's function to the G reen's function de ned only inside the cluster and its periodic supercell repetitions. This constraint is realized by the cluster self energy which plays the role of the Lagrange multiplier<sup>21,22,23</sup>. Di erentiation of this functional gives the CDMFT equations. Viewed as an approximation to the Baym-Kadano functional for the full lattice, this procedure may seem a bad approximation<sup>24</sup>. However, this construction of the functional should be viewed as an approximation to the exact e ective action for local quantities and CDMFT uses it precisely for such a purpose.

The functional approach is useful because it clari es the level of approximation used in treating the broken symmetry state. In the case that we consider in this paper, all the Hartree graphs are added to the functional (see Eq. 11). The E-DM FT  $^{6,8,21,25}$  includes additional graphs to the Hartree terms, but the quality of the results presented below show that they would make a very sm all contribution.

## C. An Exact D iagonalization A lgorithm

For the purpose of practical in plem entation of the algorithm it is convenient to consider the cluster e ective action to arise from a generalized in purity H am iltonian,

Here,  $_k$  represents the dispersion of an auxiliary noninteracting bath and  $V_k^h$ ; is the hybridization matrix between the bath and the in purity cluster. The second and third terms include all the intra-cluster interaction terms. In  $\hat{E}$  we lump together the cluster hopping matrix and chem ical potential, as well as the H artree terms s arising from non-local interactions between clusters. For the EHM

$$E = E^{00} + V \qquad X \\ h_{j^{0};0 i} \qquad (11)$$

where  $hn_j \circ i$  is computed by using the translational invariance of the system at the level of the superlattice.

In term s of the impurity m odel the param etrization of the W eiss eld function is readily obtained as,

$$\hat{G}_{0}^{1}(i!_{n}) = i!_{n} \quad \hat{E}^{(i!_{n})};$$
 (12)

where the hybridization function is given by

; 
$$(i!_{n})[_{k};V_{k}^{h};] = \frac{X}{\underset{k}{\overset{V_{k}}{\overset{h}{;}}, V_{k}^{h};}} \frac{V_{k}^{h};V_{k}^{h}}{i!_{n}}:$$
 (13)

Thus the algorithm involves determining the bath parameters  $_{k}$  and  $V_{k}^{h}$ ; self consistently subject to the condition given by Eq. 7. Our in plementation relies on the solution of the inpurity model using exact diagonalization<sup>11</sup>. Starting with an initial guess for the bath parameters we obtain the cluster self energy  $^{\circ}_{c}$ , and using the self consistency condition determine a new W eiss eld,  $\hat{G}_{0}^{-1}$  (i!  $_{n}$ )<sup>new</sup>. In turn, this de ness a new hybridization function  $^{\circ}$  (i!  $_{n}$ )<sup>new</sup>. To close the self consistency loop we project onto a nite subspace of bath

size N  $_{\rm b}$  . This projection is carried out using a conjugate gradient m in imization of the following distance function,

$$D = \frac{1}{(n_{m ax} + 1) N_{b} N_{c}} \int_{n=0}^{n_{M ax}} (i!_{n})^{new} (i!_{n})^{N_{b}}$$
(14)

where  $n_{m ax}$  is the number of grid points on the M atsubara axis. A lthough we study the CDMFT equations only at zero temperature, the self consistency equations are solved on the M atsubara axis.

III. RESULTS FOR THE HUBBARD MODEL 
$$(V = 0)$$

In order to highlight the di erences between the single in purity (LISA) and cluster dynamical mean eld schemes we present results obtained for the local spectral gap as a function of the onsite C oulomb repulsion U. To keep the computational cost similar, we initially x the total number of sites in the cluster and bath,  $N_s = N_c + N_b = 6$ , across schemes. The exact result

for the gap is known from Bethe ansatz and is given by<sup>26</sup>

$$(U) = \frac{16t^2}{U} \int_{1}^{Z_{1}} \frac{p \frac{1}{y^2 - 1}}{\sinh(2 - ty = U)} dy$$
(15)

FIG.1: Spectral gap as a function of U/t for the half led H ubbard m odel.

Fig.1 shows that there is a characteristically di erent behavior between the single in purity ( $N_c = 1$ ) and cluster schemes ( $N_c = 2$ ). In the single in purity case, for U & 7.5t the gap follows the exact result, whereas for U . 7t it reduces to values much sm aller than the exact gap and approaches zero. For the range 7t . U . 7.5t we observe a coexistence of the gapless and gapful phases. This transition from an insulating to a metallic phase is an artifact of the mean eld approach which incorporates the physics of higher dimensions where the M ott transition is indeed present. On the other hand, CDM FT com pares excellently to the exact gap and an insulating solution exists through all nite values of U, in agreem ent with the well known physics of the one dimensional Hubbard model. We measure the half spectral gap as the point where the strength of the lowest frequency pole falls to 9% of its peak height. This percentage is arrived at by requiring that the gap at strong coupling be xed at the exact value. We also nd, as expected from the cavity construction and noted recently<sup>24</sup>, that in the case of CDM FT, the bath only couples to sites on the boundary of the cluster, whereas for other cluster methods such as the dynam ical cluster approximation (DCA) all the sites in the cluster are equivalently coupled to the bath. The self consistent procedure is robust and generates these two di erent kinds of solutions regardless of the nature of the starting guess.

FIG.2: Im aginary part of the onsite G reen's function (left colum n) and realpart of the nearest neighbor G reen's function (right colum n) on the M atsubara axis for di erent values of U (in units of t).

To further illustrate the perform ance of the CDMFT m ethod, in Fig. 2 we com pare the onsite as well as nearest neighbor G reen's functions on the M atsubara axis to those we obtain using the DMRG method. The calculation of dynam ical correlation functions with in the DMRG m ethod is carried out by using the nite size algorithm<sup>15</sup> combined with the Lanczos vector method<sup>16,17</sup>. The results shown in the gures are those for chains with 18 sites and open boundary conditions. We verify that the results are close to those found by even longer chains and hence representative of the system in the therm odynam ic lim it. To highlight the role of the bath within the CDMFT method, we also overlay results obtained from exact diagonalization (ED) of a cluster of size  $N_c = 2$ , but without the bath. As U decreases we expect the di erence between onsite G reen's functions from the isolated cluster (ED) and the DMRG to increase, since the physics becom es less local. The contribution of the bath in CDMFT therefore becomes more signi cant with decreasing U and shows a system atic improvement with

FIG. 3: Deviation of LISA and CDM FT G reen's functions from the DM RG results as a function of the bath size Nb.

bath size as will be discussed later. Throughout the range of U we consider, the in aginary part of the onsite G reen's function computed using CDM FT matches remarkably well with the DMRG curve. On the other hand a com – parison for the realpart of the nearest neighbour G reen's function shows that the self consistent CDM FT solution achieves only a marginal in provement over the ED calculation for small U and alm ost none for large U. It can be clearly seen that the single in purity approach (LISA) performs poorly for the onsite G reen's function for all U, except when U is large. Likew ise, the nearest neighbor G reen's function com puted using LISA agrees poorly with the exact result throughout the entire range in U.

An important question to address is the issue of convergence and the nature of the self consistent solution as a function of the size of the e ective in purity cluster and bath allotted in each case. In order to nd a satisfactory self consistent solution, we did that the size of the Hilbert space allotted to the bath has to be at least comparable to that alloted to the cluster itself. For instance, clusters of size  $N_c = 2$  require a minimum bath of size N<sub>b</sub> = 4 for good convergence. Even and odd clusters show qualitatively di erent types of solutions, as we discuss further below. In Fig. 3 we plot , a measure of the deviation of the LISA and CDMFT solutions for the onsite and nearest neighbor G reen's function from accurate results obtained using DMRG, as a function of the bath size N<sub>b</sub>. Thism easure , is de ned as the integrated absolute di erence between the CDMFT (or LISA) and DMRG Green's functions.

Let us rst discuss the results for the strong coupling case (U = 12t). The onsite G reen's function computed using LISA compares excellently with DMRG and this continues to be so with the CDMFT method. There is practically no dependence of on the bath size. For the o site G reen's function, shows a system atic reduction with increasing cluster size, but remains fairly independent of the bath size.

For weak coupling, both LISA and CDMFT become exact. The toughest case is when U is of the order of the bandw idth; so in the following we discuss the results for U = 2t. For even clusters, we nd that for the onsite G reen's function shows a system atic decrease with increasing bath size once a m inim um bath size is reached.

On the other hand, for the o site G reen's function shows no de nite trend with increasing bath size.

FIG.4: From left to right we show the local spectral functions for sites one through three in a cluster of size N  $_{\rm c}$  = 3. The bath size is xed at N  $_{\rm b}$  = 6.

C ontrary to the expectations for a mean eld solution, even cluster sizes (N  $_{\rm c} = 2;4$ ) show no explicit local spin sym m etry breaking. 0 dd clusters (N  $_{\rm c}$  = 3;5) show sim ilarbehavior for sm all bath sizes up to N<sub>b</sub> = N<sub>c</sub>. For larger bath sizes, N<sub>b</sub>  $N_c$ , and large enough U, the behavior of the local spectral function is spin dependent as can be seen from Fig. 4 for U = 12t. 0 dd clusters with broken symmetry are clearly inconsistent with cluster periodicty and consequently show poorer convergence. Thus, for all even clusters and odd clusters with small enough bath sizes, the one dimensional character of the problem is dom inant over the role of the bath and prevents the self consistency from showing explicit spin symmetry breaking. On the other hand, odd clusters (we were able to test only the case  $N_c = 3$ ) with large U and a su ciently large bath show a symmetry broken solution consistent with the mean eld approach.

The e ect of the bath for  $N_c = 3$  has an even more dram atic consequence at smaller U. As opposed to even clusters which correctly see only an insulating solution in one dimension, we see both a metallic and an insulating solution for  $N_b = 5$  and U = 3t. In the region of coexistence, the metallic solution shows a better convergence than the insulating one. Thus, the improvement gained in going from LISA to  $N_c = 3$  is that the region of coexistence moves to smaller U's and the insulating solution is present all the way upto U = 0. Small baths, due to the absence of enough degrees of freedom to impose a mean

eld character to the solution, show an insulating state throughout the range in U. Beyond N  $_{\rm c}$  = 3 for large enough odd clusters we expect to see only an insulating solution for all U > 0.

IV.

FIG. 5: Im aginary part of the onsite G reen's function (left column) and realpart of the nearest neighbor G reen's function (right colum n) on the M atsubara axis for di erent values of V in the SDW phase.

FIG.6: Real part of the onsite G reen's function in the CDW phase.

In this section we study the performance of cluster mean eld methods as applied to the Extended Hubbard model. This model constitutes a natural test case since the non-local nearest neighbor C oulom b repulsion am ong di erent sites within the cluster can be accounted for exactly.

Athalf lling, for large enough U (strong coupling), the system goes through a st order transition from a spin

FIG. 7: Im aginary part of the onsite G reen's function in the CDW phase.

FIG.8: Realpart of the nearest neighbor G reen's function in the CDW phase.

density wave (SDW) to a charge density wave (CDW) ordered state at roughly  $V = U = 2^{27,28,29}$ . We work in this regime, by xing U = 12t and scanning through the nearest neighbor C oulom b repulsion V. The C D M FT m ethod shows a clear signature of this transition with a cluster as small as  $N_c = 2$ . In Fig. 5 we report a comparison of the imaginary part of the onsite G reen's function and the real part of the near neighbor G reen's function in the SDW phase. As seen in the V = 0 case, the comparison with DMRG is better for the form er than the latter. We note that with increasing V the o site G reen's function com pares better with the DMRG result. Figs. 6,7 and 8 compare the Green's functions within the CDW phase. A cross the range in V, the agreem ent with DMRG is so remarkable that only one set of curves are discernable within the gures. In particular, Fig. 6 shows the real part of the onsite G reen's function which is zero in the SDW phase but acquires a non-zero value in the CDW phase. This indicates a breaking of local particle-hole symmetry of the system that is now conserved only on the average every two sites. Notice how the curves for di erent values of V cross, de ning a characteristic scale approximately equal to U. The versatility of CDMFT in being able to treat the ordered phase stems from the fact that it only assumes supercell periodicity and consequently allows for complicated ordered states within a cell. This is in contrast to the DCA method that assumes fullperiodicity of the lattice, and therefore requires a ne discretization in momentum space to adequately capture the discontinuities in the Brillouin zone that appear with the emergence of short range ordered phases.

### V. CONCLUSIONS AND OUTLOOK

FIG. 9: Schematic representation of an RG procedure intended to reach large cluster sizes.

We have shown that the CDMFT method produces remarkably good results when tested in one dimensional systems. This is very encouraging, since one would expect mean eld methods to perform even better as the dimensionality increases. We saw that even the smallest possible cluster size ( $N_c = 2$ ) along with a self consistent bath of modest size allows for an accurate determination of onsite correlations, while the osite quantities in prove system atically with increasing cluster size. Further, the success of our extension of the CDMFT equations to describe the discrete broken symmetry of the CDW order clearly demonstrates the power of the method to incorporate short range correlations.

Following the example of the EHM, with the simplest kind of short range correlation, it should be possible to treat the physics of more complicated ordered phases as well as unit cells of realistic materials within the cellular mean eld approach. The main obstacle in this program is the computational e ort that goes into solving the self consistent equations for the large clusters required by real world applications. This calls for a system atic approach that blends together cluster dynam ical mean ekl and renorm alization group  $ideas^{15,30}$  to select the most relevant degrees of freedom to represent a cluster.

We suggest that the CDMFT approach can be used iteratively in complete analogy with the density matrix renorm alization group approach. It is useful to compare the similarities and di erences between these two methods. In both of them, one improves on the exact diagonalization of a small nite size system by embedding the small system in a larger one; an embedding which can be described by a reduced density matrix. Within DMRG the density matrix is determined by an exact diagonalization of the larger system containing the subsystem of interest. In CDMFT, one can approxim ate the density matrix by modelling the environment with a Gaussian Weiss eld.

The CDMFT assumption of a self consistent gaussian bath as the environm ent, that one can integrate out exactly in order to de ne a reduced density matrix for the cluster, becom es m ore and m ore accurate as the dim ensionality increases. This choice of bath is optimum in a dynamicalmean eld sense (optimized for the com putation of the local one particle G reen's function of the cluster) and sidesteps the conventional DMRG procedure for building the reduced density matrix out of a few target states. Further, the DMRG prescription<sup>15</sup> of selecting the states for which the reduced density matrix has the largest eigenvalues allows for a truncation of the cluster Hilbert space while retaining the relevant physical inform ation. In Fig. 9 we indicate schem atically how such a method would proceed by doing CDMFT on sm all clusters, truncating their H ibert space using the DMRG prescription and nally using them as building blocks of even larger clusters. This procedure can be repeated until either a desired cluster size or convergence in a certain observable of interest is reached. W e believe this scheme should open new vistas for num erical renormalization group calculations of realistic systems in two and three dimensions.

## \*

## APPENDIX A:DETERM INATION OF THE CLUSTER SELF ENERGY

The rst step in the CDMFT iterative scheme is to compute the cluster self energy  $\hat{}_c$  for an initial guess of the bath parameters. This can be done using Eq. 7 by subtracting the inverses of the numerically determined cluster G reen's function ( $\hat{G}_{imp}(i!_n)$ ) from the exactly

known W eiss eld. A lthough this is accurate enough for m ost purposes, when the results are sm all, it can introduce num erical errors. To deal with this, an alternative procedure was proposed in the context of the single im purity A nderson m odel<sup>31</sup>. The idea is to isolate contributions to the self energy com ing purely from the hybridization and the interactions. The term s arising from the interactions can be written as ratios of correlation functions of com posite operators leading to a m ore stable num erical procedure. W e generalize this procedure to the cluster A nderson in purity m odel to write the self energy in the form

$$^{\circ}_{c}(i!_{n}) = ^{\circ}_{U}(i!_{n}) + ^{\circ}_{V}(i!_{n})$$
 (A1)

where

$$V_{\rm V} (i!_{\rm n}) = K \stackrel{\circ}{(i!_{\rm n})} \hat{G}_{im_{\rm p}}^{1} (i!_{\rm n}) (A3)$$

and

$$F = c c^{y} c ; c^{y}$$

$$K = V \circ c n \circ ; c^{y}$$
(A 4)

$$+ V \circ n \circ c ; c^{Y}$$
 (A 5)

Here A;B denotes the G reen's function of operators A and B. This m ethod of computing the self energy is particularly robust for sm all values of U = t, when the self energy is relatively sm all in m agnitude, as compared to the direct approach.
