

Many-Body Density Matrices for Free Fermions

Siew-Ann Cheong and Christopher L. Henley

Laboratory of Atomic and Solid State Physics, Cornell University

(Dated: April 14, 2024)

Building upon an analytical technique introduced by Chung and Peschel, Phys. Rev. B 64, art. 064412 (2001), we calculated the many-body density matrix ρ_B of a finite block of B sites within an infinite system of free spinless fermions in arbitrary dimensions. In terms of the block Green function matrix G (whose elements are $G_{ij} = \langle c_i^\dagger c_j \rangle$, where c_i^\dagger and c_j are fermion creation and annihilation operators acting on sites i and j within the block respectively), the density matrix can be written as $\rho_B = \det(\mathbb{I} - G) \exp[\sum_{ij} (\log G (\mathbb{I} - G)^{-1})_{ij} c_i^\dagger c_j]$. Our results suggest that Hilbert space truncation schemes should retain the states created by a subset of the c_i^\dagger 's (in any combination), rather than selecting eigenvectors of ρ_B independently based on the eigenvalue.

I. INTRODUCTION

Exact solutions are hard to come by in many-body problems, and every so often we have to resort to numerical solutions. The traditional approaches, applied to finite systems, are exact diagonalization and quantum Monte Carlo. For quantum lattice models of fermions, the former is constrained by the size of the Hilbert space, which grows exponentially with the number of sites, while the latter is plagued by the 'minus-sign problem'. For quantum lattice models of bosons, the Hilbert space is infinite-dimensional even for finite systems. In either case, because of the enormous computational complexity involved, there is no hope of getting to the thermodynamic limit of infinite system size. In view of these difficulties, one then hopes for the next best thing: approximate solutions that capture the essence of the physics.

This is where renormalization group (RG) approaches come in. In such approaches^{1,2,3,4,5,6,7,8,9,10,11} to the approximate solution of otherwise intractable problems, the size of the Hilbert space is kept in check by aggressive truncation, with the hope that the small number of states kept will reproduce the more important features of the physics. Whatever the RG scheme, ultimately its success will lie in how the truncation is done. Since the quantum-mechanical state of a block embedded in a larger system must in general be described by a density matrix, it is therefore natural to use it to guide the truncations.

With the goal of understanding the structure and spectrum of the density matrix, and their implications on RG truncation schemes in mind, Peschel et al. calculated exactly the half-chain density matrix for several models.^{12,13,14} For a chain of coupled harmonic oscillators and spinless Bogoliubov fermions, they found that the half-chain density matrices can be expressed exactly as the exponential of a pseudo-Hamiltonian, whose spectrum is generated by a set of independent bosonic and fermionic operators respectively. In this paper, we pursue

their analysis further for a system of free spinless fermions to obtain a closed-form formula relating the density matrix ρ_B of a subsystem and the subsystem Green function matrix G (to be defined in Section II C).

The organization of the paper will be as follows: we will start in Section II by reviewing the density matrix formulation of quantum mechanics, and how the density matrix ρ_B of a subsystem can be obtained from the density matrix ρ_0 of the overall system. Following this, we will describe an alternative approach to calculating the density matrix elements as expectations of referencing operators. We shall show that the real-space structure, and the strong signs that point to a closed-form expression for ρ_B , is most readily discerned within this alternative formulation. Then, in Section III, we derive this closed-form expression for ρ_B in terms of the subsystem Green function matrix G by adapting the technique put forward by Chung and Peschel.¹⁴ The existence of such a relation between ρ_B and G tells us that ρ_B is completely determined by its 0- and 1-particle sectors. We discuss the implications of this in Section IV, where we illustrate how the eigenvectors and eigenvalues of the $(F > 1)$ -sectors of ρ_B can be constructed out of the eigenvectors and eigenvalues of the 1-particle sector. We also show how symmetries of the Hamiltonian that are realized in ρ_B affect the pattern of degeneracies in the eigenvalues of these sectors, an understanding of which is important in formulating a consistent truncation scheme.

II. DENSITY MATRIX OF A FINITE BLOCK

In this section, we first review the density matrix notions that will be used throughout this paper. Following this we develop the first of our two paths to calculate the density matrix ρ_B for a particular block within a large system of non-interacting fermions. By analyzing the index structure of the matrices involved, we arrived at a conjecture for a closed-form expression for the 1-particle

sector of the block density matrix ρ_B in terms of the block Green function matrix G .

A. Density Matrix Formulation of Quantum Mechanics

In quantum mechanics one distinguishes between pure states, which occur, for example, at $T = 0$ when the system is totally decoupled from the rest of the universe, and mixed states, which occur, for example, at $T > 0$ when the system is in thermodynamic equilibrium with the rest of the universe. A pure state can be described by a wavefunction ψ_i in the usual formulation of quantum mechanics, whereas a mixed state cannot. Both type of states are treated on equal footing in the density matrix formulation of quantum mechanics, in which the state of a system is described by a density matrix ρ_0 (see, for example, Ref. 15). In this formulation of quantum mechanics, the expectation of an operator A in a state described by ρ_0 is given by

$$\langle A \rangle = \text{Tr}(\rho_0 A); \quad (2.1)$$

If the state so described is pure, i.e. given in the usual formulation by the wavefunction ψ_i , so that $\langle A \rangle = \langle \psi_i | A | \psi_i \rangle$, then it is clear that $\rho_0 = |\psi_i\rangle\langle\psi_i|$.

In this paper, we shall be mainly interested in a finite subsystem of B sites, which we call the block, embedded within a larger system of N sites, with periodic boundary conditions in dimensions. The latter can then be taken to the thermodynamic limit of infinite number of sites, i.e. $N \rightarrow \infty$. The system minus the block is called the environment of the block. If the overall system is known to be in a pure state ψ_i , then in general the quantum-mechanical state of the block cannot be described by a pure state wavefunction. Instead, the mixed state of the block must be described by a block density matrix ρ_B (see arguments in Ref. 16), so defined that

$$\langle A \rangle = \text{Tr}(\rho_B A); \quad (2.2)$$

if the operator A acts entirely within the block.

There are two useful formulas to relate the block density matrix ρ_B to the density matrix ρ_0 of the entire system. The first formula, which we will use in Section III, follows from (2.1) and (2.2). Using the subscripts B and E respectively to make the trace over the degrees of freedom associated with the block and its environment more explicit, we can rewrite (2.1) as

$$\langle A \rangle = \text{Tr}(\rho_0 A) = \text{Tr}_{B,E}(\rho_0 A); \quad (2.3)$$

Since A does not act on the environment, we can trivially trace over environmental degrees of freedom to get

$$\langle A \rangle = \text{Tr}_B [f[\text{Tr}_E(\rho_0)] A]; \quad (2.4)$$

Comparing this with (2.2), we find a consistent expectation for A whether it is taken over the entire system or

just over the block, if the block density matrix is defined as

$$\rho_B = \text{Tr}_E(\rho_0); \quad (2.5)$$

The second formula for ρ_B allows us to write down its matrix elements explicitly when the overall system is in a pure state. To arrive at this formula, let us first note that any pure state of the overall system can be written as $\psi_i = \sum_b \psi_{bi} \phi_b$, where ψ_{bi} is a complete orthonormal (many-body) basis for the block, and ϕ_b is the (unnormalized) state of the environment associated with the state ψ_i on the block. Using this form for ψ_i in (2.1), we find that

$$\langle A \rangle = \sum_{b,b'} \langle \psi_{bi} | A | \psi_{b'i} \rangle \langle \phi_b | \phi_{b'} \rangle = \text{Tr}_B(\rho_B A) \quad (2.6)$$

if the block density matrix ρ_B is defined such that

$$(\rho_B)_{b'b} = \langle \psi_{bi} | A | \psi_{b'i} \rangle; \quad (2.7)$$

i.e. the matrix element of ρ_B between ψ_{bi} and $\psi_{b'i}$ is none other than the overlap between their associated environmental states ϕ_b and $\phi_{b'}$.

B. Free Spinless Fermions

Let us now apply (2.7) to calculate the block density matrix from the ground state of a ring of $N+1$ free spinless fermions, the simplest realization of which is described by a translationally-invariant Hamiltonian with nearest-neighbor hopping

$$H = \sum_{\langle ij \rangle} (c_i^\dagger c_j + c_j^\dagger c_i); \quad (2.8)$$

where c_i and c_i^\dagger are the fermion annihilation and creation operators acting on site i , and $\langle ij \rangle$ runs once over each pair of neighbor sites.

The Hamiltonian given in (2.8) is diagonal in momentum space, and can be written as

$$H = \sum_k \epsilon_k^\dagger c_k^\dagger c_k; \quad (2.9)$$

Here

$$\begin{aligned} c_k &= \frac{1}{\sqrt{N}} \sum_j c_j e^{ik \cdot r_j}; \\ c_k^\dagger &= \frac{1}{\sqrt{N}} \sum_j c_j^\dagger e^{-ik \cdot r_j} \end{aligned} \quad (2.10)$$

are the momentum space annihilation and creation operators, r_i is the position of site i , and ϵ_k the single-particle energy associated with wavevector k . The ground state of such a system is just a Fermi sea

$$|F\rangle = \prod_{k \leq k_F} c_k^\dagger |0\rangle; \quad (2.11)$$

where ϕ_i is the vacuum, and the product is over the wavevectors inside the Fermi surface.

As noted in (2.7), when the ground state wavefunction is written as $\phi_F = \sum_b \phi_b \phi_b^0$, the block density matrix elements are $(\rho_B)_{b^0 b} = \langle \phi_b \phi_b^0 |$. When dealing with a finite block and an infinite environment, it makes no sense to evaluate these environmental overlaps by first calculating ϕ_b and ϕ_b^0 . Instead, we find that it is possible to evaluate such environmental overlaps with the help of operator products that are defined entirely within the block. To do so, let us first write the many-body states ϕ_i on the block in the occupation number representation as $\phi_i = \prod_j n_j^0 \prod_b \phi_b$ where $n_j^0 = 0$ or 1 depending on whether the site j on the block is empty or occupied in the state ϕ_i . We then define the referencing operators

$$K_b = \sum_{j=1}^B n_j^b c_j + (1 - n_j^b) c_j^\dagger c_j^\dagger; \quad (2.12)$$

such that the effect of K_b acting on a state ϕ_i is $K_b \phi_i = \sum_{b^0} \phi_{i_b}^0$, where $\phi_{i_b}^0$ is the reference state for which all sites on the block are empty. Letting K_b act on ϕ_F gives $K_b \phi_F = \sum_{b^0} K_b \phi_b \phi_b^0 = \sum_b \phi_b \phi_b^0$. Hence, in terms of the operators K_b and their conjugates K_b^\dagger , the density matrix elements are found to be

$$(\rho_B)_{b^0 b} = \langle \phi_b \phi_b^0 | = \langle \phi_F | K_b^\dagger K_b | \phi_F \rangle = \langle \phi_F | K_b^\dagger | \phi_F \rangle; \quad (2.13)$$

From the way the operators K_b are defined, we know that ρ_B is real and symmetric. Furthermore, $(\rho_B)_{b^0 b}$ vanishes if the states ϕ_i and ϕ_i^0 do not contain the same number of fermions F . Consequently, the non-zero matrix elements of ρ_B are found in a total of $(B+1)$ submatrices along the diagonal, corresponding to the various F -particle sectors, for $F = 0, 1, \dots, B$. We shall call such submatrices $\rho_{B,F}$, and their eigenvalues the density matrix weights $w_{B,F,l}$, where $l = 1, \dots, \text{rank}(\rho_{B,F})$.

C. Conjecture Based on Index Structure

In general, for a block of B sites, there are a total of 2^B K_b operators we need to write down explicitly to calculate the 2^B density matrix elements. For large blocks, this is extremely tedious and has to be automated (see Appendix A), but for small blocks, it is not difficult to work out exact expressions for $(\rho_B)_{b^0 b}$ in terms of the 2n-point functions

$$G_{ij} = \langle c_i^\dagger c_j \rangle; \quad (2.14a)$$

$$G_{ijk1} = \langle c_i^\dagger c_j^\dagger c_k c_1 \rangle = (-1)^{\frac{2(2-1)}{2}} \frac{G_{ik} G_{j1}}{G_{jk} G_{j1}}; \quad (2.14b)$$

$$\begin{aligned} G_{ijk1m n} &= \langle c_i^\dagger c_j^\dagger c_k^\dagger c_l c_m c_n \rangle \\ &= (-1)^{\frac{3(3-1)}{2}} \frac{G_{i1} G_{jm} G_{jn}}{G_{j1} G_{jm} G_{jn}}; \end{aligned} \quad (2.14c)$$

and so forth, where $i, j, k, l, \dots = 1, \dots, B$ are sites on the block. As shown explicitly above, the 2n-point functions $G_{i_1 i_2 \dots j_1 j_n}$ Wick factorizes into sums of products of 2-point functions G_{ij} for our non-interacting system, with an overall fermion factor of $(-1)^{n(n-1)/2}$.

At this point let us note that since the 2-point functions G_{ij} are labelled by two indices, it is convenient to organize them into a system Green function matrix G given by

$$G = \begin{pmatrix} G_{11} & G_{12} & \dots & G_{1B} \\ G_{21} & G_{22} & \dots & G_{2B} \\ \vdots & \vdots & \ddots & \vdots \\ G_{B1} & G_{B2} & \dots & G_{BB} \end{pmatrix}; \quad (2.15)$$

of which

$$G = \begin{pmatrix} G_{11} & G_{12} & \dots & G_{1B} \\ G_{21} & G_{22} & \dots & G_{2B} \\ \vdots & \vdots & \ddots & \vdots \\ G_{B1} & G_{B2} & \dots & G_{BB} \end{pmatrix} \quad (2.16)$$

is its restriction to the block. We call G the block Green function matrix. As a result of the translational invariance of H , G is also translationally invariant. In real space, this means that its matrix elements $G_{ij} = \langle c_i^\dagger c_j \rangle$ are functions only of $r_i - r_j$. When G is restricted to the block to give G , however, this translational invariance is lost due to the fact that the presence of a block in the system allows an unambiguous definition of the origin.

Anyway, from (2.12) and (2.13), we see on the one hand that $(\rho_B)_{b^0 b}$ can be written as sums of 2n-point functions which themselves factor into sums of products of 2-point functions and so we find that $(\rho_B)_{b^0 b}$ are all functions of G_{kl} . On the other hand, the 1-particle sector of ρ_B contains matrix elements $(\rho_B)_{b^0 b}$ connecting the states ϕ_i and ϕ_i^0 , which contain one particle each at sites, say, i and j respectively. Therefore, the matrix elements within $\rho_{B,1}$ may be indexed using i and j instead of b and b^0 . Diligently writing down the polynomial expressions

$$\begin{aligned} (\rho_{B,1})_{ij} &= \sum_{k_1, l_1} X^{(1)}_{ij, k_1 l_1} G_{k_1 l_1} + \\ &+ \sum_{k_1, k_2; l_1, l_2} X^{(2)}_{ij, k_1 k_2 l_1 l_2} G_{k_1 l_1} G_{k_2 l_2} + \dots \\ &+ \sum_{k_1, \dots, k_B; l_1, \dots, l_B} X^{(B)}_{ij, k_1 \dots k_B l_1 \dots l_B} G_{k_1 l_1} \dots G_{k_B l_B}; \end{aligned} \quad (2.17)$$

we find that: (a) the coefficients $\binom{n}{ij;k_1 \dots k_l; n_1}$ are independent of i and j ; and (b) indices other than i and j always appear in pairs, as if they are summed over.

Exhaustively comparing the matrix elements of $B_{i,j}$ and powers of G for $2 \leq B \leq 5$, we find that

$$\begin{aligned} B_{i,j} = & G + G^2 - G \text{Tr}(G) + \\ & G^3 - G^2 \text{Tr}(G) - \frac{1}{2} \text{Tr}(G^2) [\text{Tr}(G)]^2 - G + \\ & G^4 - G^3 \text{Tr}(G) - \frac{1}{2} \text{Tr}(G^2) [\text{Tr}(G)]^2 - G^2 \\ & - \frac{1}{3} \text{Tr}(G^3) - \frac{1}{2} \text{Tr}(G) \text{Tr}(G^2) + \frac{1}{6} [\text{Tr}(G)]^3 - G + \end{aligned} \quad (2.18)$$

What is most fascinating about this series is that for $B = 2$, (2.12) and (2.13) tell us that $B_{i,j}$ can be at most $O(G^2)$, since its matrix elements never contain terms with more than two creation and annihilation operators each. Yet (2.18) is perfectly valid for $B = 2$, because terms higher order in G vanish. For $B = 3$ and $B = 4$, we find similarly that terms higher order than $O(G^3)$ and $O(G^4)$ vanishes, respectively. If we conjecture that (2.18) gives the leading terms to an infinite series that holds true for all $B > 5$, then we can factorize it into

$$B_{i,j} = (G + G^2 + G^3 + \dots) \exp \left(\text{Tr}(G) + \frac{1}{2} G^2 + \frac{1}{3} G^3 + \dots \right) \quad (2.19)$$

Noting that the series inside the trace is just $-\log(1 - G)$, (2.19) can be compactly written as

$$B_{i,j} = G (1 - G)^{-1} \det(1 - G) \quad (2.20)$$

III. DERIVATION AND PROPERTIES OF B

In passing from (2.18) to (2.20), a leap of faith was required, and it would appear forbiddingly difficult to actually prove (2.20) for arbitrary block sizes B , by the algebraic manipulations used in Section II C. Fortunately, an alternate technique introduced by Chung and Peschel¹⁴ can be adapted and extended for calculating the density matrix of a finite block, although it comes with its own set of technical difficulties. It turns out that if the whole system were in the Fermi sea ground state, the derivation would require the inversion of singular matrices. In the end, the singularities do cancel and give a well-defined answer, but a regularization is needed to avoid divergences in the intermediate steps. The most natural way to do so would be to generalize our problem to nonzero temperature, in which case the limit $T \rightarrow 0$ then provides the needed regularization.¹⁹

In essence, the calculations is just that of evaluating a Gaussian integral with the usual shift in integration variables. However, because we are dealing with fermions, whose creation and annihilation operators anticommute rather than commute, additional machinery is needed to accomplish the feat of Gaussian integration. After casting the system density matrix ρ_0 as a Gaussian of

the fermion operators, we introduce fermionic coherent states with the aid of anticommuting Grassmann variables. The matrix elements of ρ_0 between such coherent states, obtained via a translation machinery, are similarly of Gaussian form, but are now easier to handle. A Gaussian integration over the environmental degrees of freedom then yields elements of the block density matrix B , following which reverse translation gives B proper.

A. Exponential Form for ρ_0

To get the calculations underway, we consider the grand-canonical $T > 0$ density matrix ρ_0 of the overall system that the block is embedded in. As always, this is given by

$$\rho_0 = Q^{-1} \exp[-(H - F)] \quad (3.1)$$

where $\beta = 1/k_B T$, μ is the chemical potential, and $F = \sum_k \epsilon_k^\dagger c_k^\dagger c_k$ is the fermion number operator. The prefactor Q^{-1} in (3.1) is just the reciprocal of the grand partition function, to ensure that $\text{Tr}(\rho_0) = 1$.

The notations can be made more compact if we introduce the matrices G and its Fourier transform \tilde{G} , such that

$$\rho_0 = Q^{-1} \exp \sum_{i,j} G_{ij} c_i^\dagger c_j = Q^{-1} \exp \sum_k \tilde{G}_{kk} c_k^\dagger c_k; \quad (3.2)$$

where we have made use of the fact that $H = F$, and hence \tilde{G} is diagonal in momentum space. The matrix elements of G can be read off from (2.8) as

$$G_{ij} = \begin{cases} \epsilon_i & ; \text{ if } i = j; \\ t_{ij} & ; \text{ if } i \text{ and } j \text{ are nearest neighbors;} \\ 0 & ; \text{ otherwise,} \end{cases} \quad (3.3)$$

while those of \tilde{G} can be read off from (2.9) as

$$\tilde{G}_{kk} = E_k; \quad (3.4)$$

where E_k is the single-particle energy measured relative to μ .

In order to prove our conjecture (2.20), it is clear that we need to somehow relate B to G . To do this, let us note that since G is translationally invariant, its Fourier transform \tilde{G} is diagonal in momentum space, with matrix elements given in the grand-canonical ensemble as

$$G_{kk} = \langle c_k^\dagger c_k \rangle = \frac{1}{\exp E_k + 1}; \quad (3.5)$$

observing which we find that

$$G_{kk} = \exp(\tilde{G}_{kk}) / \exp(\tilde{G}_{kk} + 1); \quad (3.6)$$

But since both G and \tilde{G} are diagonal matrices, we have the relation

$$\tilde{G} = G (1 - G)^{-1}; \quad (3.7)$$

decoherence submatrix of $(\mathbb{1} + e)$, obtained by restricting the row index to range only over sites on the block and the column index to range only over sites in the environment.

D. Tracing Down

With (3.15) and (3.16), the block density matrix elements can then be written as

$$\langle j_B | j^0 \rangle = Q^{-1} e^{\sum_i (A^{-1})^0_{ij} \langle d | d \rangle e^{B^{-1} B^T} C} ; \quad (3.17)$$

Here we have made use of the fact that since the Grassmann variables occur quadratically in each term in the exponential, they commute with one another and we may thus factor the exponential as if it is an exponential of c-numbers.

By performing a shift of the integration variables and ψ , and then evaluating the Grassmann Gaussian integral using (3.12), we find that

$$\langle j_B | j^0 \rangle = Q^{-1} \det C e^{\sum_i (A^{-1} B C^{-1} B^T)^0_{ij}} ; \quad (3.18)$$

which parallels Eq. (14) in Ref. 14. From (3.18), we see that the expression for $\langle j_B | j^0 \rangle$ involves only the Grassmann coordinates ψ_i and ψ^0_i associated with sites on the block. This is good. But it also involves the decoherence submatrix B as well as the environment submatrix C , with the latter appearing both in the exponential as well as in the normalization constant. These matrices have indices that range over sites outside the block, which we are supposed to have traced out and gotten over with.

Indeed, this must have been successfully done, since $A^{-1} B C^{-1} B^T$ is a $B \times B$ matrix whose indices range only over sites on the block. In fact, using (B5) in Appendix B, we can express this matrix entirely in terms of submatrices on the block, and write (3.18) as

$$\langle j_B | j^0 \rangle = Q^{-1} \det C e^{\sum_i (D^{-1} \mathbb{1})^0_{ij}} ; \quad (3.19)$$

where D is the block submatrix of $(\mathbb{1} + e)^{-1}$, obtained by restricting its indices to range only over sites on the block. That leaves only the $\det C$ in the normalization that we have to deal with.

To express $Q^{-1} \det C$ in terms of submatrices whose indices range only over sites on the block, we make use of the fact that

$$\begin{aligned} \text{Tr}(B) &= 1 = \sum_i \langle d | d \rangle e^{\sum_i (A^{-1} B C^{-1} B^T)^0_{ii}} \langle j_B | j^0 \rangle \\ &= Q^{-1} \det C \sum_i \langle d | d \rangle e^{\sum_i (D^{-1} \mathbb{1})^0_{ii}} \quad (3.20) \\ &= Q^{-1} \det C \det D^{-1} ; \end{aligned}$$

which means that

$$Q^{-1} \det C = \det D ; \quad (3.21)$$

With this we have succeeded in writing down a Gaussian form for the coherent state matrix elements of B involving only degrees of freedom on the block. Using the translation machinery provided by (3.10), we then establish the exponentiated form

$$B = \det D \exp \sum_{i,j} \log(D^{-1} \mathbb{1})_{ij} c_i^y c_j^0 \quad (3.22)$$

of Chung and Peschel.

At this point, let us remark that the above formula for B is of no practical use, if to find the matrix D , we actually have to evaluate the matrix $(\mathbb{1} + e)$, whose indices run over the entire system, take its inverse $(\mathbb{1} + e)^{-1}$, and then from this identify the block submatrix D . This is essentially what was done in Ref. 14, where the matrix parallel to $D^{-1} \mathbb{1}$ was computed numerically, for the case of an environment equal in size to the block. For our problem, identifying $A^{-1} B C^{-1} B^T$ as D^{-1} with the aid of our analytic relation (B5) allows us to work with arbitrary, even infinite, environment sizes.

Furthermore, armed with the relationship (3.8) obtained in Section IIIA, we can find that the normalization and matrix of coefficients appearing in (3.19) in terms of the block Green function matrix G . From

$$\mathbb{1} + e = \mathbb{1} + G(\mathbb{1} - G)^{-1} = (\mathbb{1} - G)^{-1} ; \quad (3.23)$$

we see that D is just $(\mathbb{1} - G)$ restricted to the block, i.e. $D = \mathbb{1} - G$, and consequently, $D^{-1} = (\mathbb{1} - G)^{-1}$. With this, the normalization constant for B can be written as $\det D = \det(\mathbb{1} - G)$. For the matrix of coefficients $(D^{-1} \mathbb{1})$ in the exponential, we see that

$$D^{-1} \mathbb{1} = (\mathbb{1} - G)^{-1} \mathbb{1} = G(\mathbb{1} - G)^{-1} ; \quad (3.24)$$

With this substitution, the matrix elements of B now reads as

$$\langle j_B | j^0 \rangle = \det(\mathbb{1} - G) \exp \sum_{i,j} G(\mathbb{1} - G)^{-1}^0_{ij} ; \quad (3.25)$$

so that, after using (3.10) in reverse translation, we can read off the operator form of B as

$$B = \det(\mathbb{1} - G) \exp \sum_{i,j} \log G(\mathbb{1} - G)^{-1}_{ij} c_i^y c_j^0 ; \quad (3.26)$$

In a suitable basis diagonalizing $\log G(\mathbb{1} - G)^{-1}$, this becomes

$$B = \det(\mathbb{1} - G) \exp \sum_i \lambda_i f_i^y f_i ; \quad (3.27)$$

where the f_i 's are linear combinations of c_j 's, and λ_i is the associated pseudo-energy (see (3.33) for definition). With (3.27), we see that to find B , we need only calculate the $B \times B$ block Green function matrix G from the ground state wavefunction with the aid of operators

local to the block, and diagonalize it to determine f_1 and subsequently $'_1$.

To connect this with the results that we obtained in Section II C, let us evaluate the matrix elements for the 0- and 1-particle sectors of B . Taylor expanding the exponential in (3.27) gives us

$$B = \det(\mathbb{1} - G) \prod_i (1 + (e^{-1} - 1) f_1^y f_1^i); \quad (3.28)$$

and so we see that the 0-particle sector is given by

$$B_{|0\rangle} = B_{|0\rangle} \langle 0|_B = \det(\mathbb{1} - G); \quad (3.29)$$

while in the basis diagonalizing B , the matrix elements in the 1-particle sector are given by

$$\begin{aligned} B_{|1\rangle} \langle 1|_B &= \det(\mathbb{1} - G) B_{|1\rangle} \langle 1|_B = \det(\mathbb{1} - G) \prod_i (1 + (e^{-1} - 1) f_1^y f_1^i) \\ &= \det(\mathbb{1} - G) e^{-1} \\ &= \det(\mathbb{1} - G) G (\mathbb{1} - G)^{-1} \mathbb{1}; \end{aligned} \quad (3.30)$$

This completes the proof of our conjecture at the end of Section II that as a matrix, $B_{|1\rangle}$ is related to G by (2.20).

E. The Pseudo-Energies $'_1$

With the closed-form formula (3.27) for B at hand, we are now ready to understand its structure and spectra. To begin with, we find that the exponential form

$$\begin{aligned} B &= \det(\mathbb{1} - G) \exp \sum_{ij} \log G (\mathbb{1} - G)^{-1} c_i^y c_j^5 \\ &= \det(\mathbb{1} - G) \exp \sum_{ij} c_i^y c_j^5; \end{aligned} \quad (3.31)$$

where we define the matrix to be

$$= \log G (\mathbb{1} - G)^{-1} = \log G + \log(\mathbb{1} - G); \quad (3.32)$$

implies that the weights and eigenvectors of the $(F > 1)$ -particle sectors of B are determined completely by those in the 0- and 1-particle sectors. Defining the set of pseudo-energies

$$'_1 = (\log G (\mathbb{1} - G)^{-1})_{11}; \quad (3.33)$$

for $l = 1; \dots; B$, which are the eigenvalues of $'$, and $'_0 = \log \det(\mathbb{1} - G)$, we find that the weights of the 1-particle block can be written as

$$w_1 = \exp[('_0 + '_1)]; \quad (3.34)$$

and B can be written in the form

$$B = e^{-1} \exp \sum_i (e^{-1} - 1) f_1^y f_1^i = e^{-1} \exp[H]: \quad (3.35)$$

Inspired by the resemblance of the form of B to the density matrix of a quantum canonical ensemble, we call H the pseudo-Hamiltonian.

F. Particle-Hole Symmetry at Half-Filling

To complete our understanding of the structure and spectrum of B , we want to know how symmetries of the original problem are built into B . In particular, we will consider particle-hole symmetry on a bipartite lattice, on which we define a 'charge-conjugation' operator C , with $C^2 = \mathbb{1}$.²⁰ The action of C on the coordinate space fermion operators can be defined to be

$$C c_i C = (-1)^i c_i^y; \quad C c_i^y C = (-1)^i c_i; \quad (3.36)$$

where $(-1)^i$ is defined to be $+1$ (-1) whenever the site i belongs to the even (odd) sublattice. In a d -dimensional hypercubic lattice, where the site index is $i = f_1; i_2; \dots; i_d$, the factor $(-1)^i$ is rightfully given by $(-1)^i = (-1)^{i_1 + i_2 + \dots + i_d}$.

There are two conditions, one on the dispersion relation ϵ_k , and the other on the chemical potential μ , implied by particle-hole symmetry. To derive the first condition on the dispersion relation, we note from (3.36) that in momentum space $|\mathbf{k}|$ when the lattice is a Bravais lattice $|\mathbf{k}|$ that

$$C \epsilon_k C = \epsilon_{k+Q}^y; \quad C \epsilon_k^y C = \epsilon_{k+Q}; \quad (3.37)$$

where the wavevector Q is defined by $e^{iQ \cdot \mathbf{r}_i} = (-1)^i$.²¹ We can then check, with (2.9) and (3.37), that

$$C H C = \sum_k \epsilon_{k+Q} \epsilon_k^y = \sum_{k^0} \epsilon_{k^0+2Q} \epsilon_{k^0}^y; \quad (3.38)$$

Now, from the definition of Q , it is clear that

$$\begin{aligned} \epsilon_{k^0+2Q} &= N^{-1/2} \sum_j e^{i(k^0+2Q) \cdot \mathbf{r}_j} c_j \\ &= N^{-1/2} \sum_j e^{ik^0 \cdot \mathbf{r}_j} [(-1)^j]^2 c_j = \epsilon_{k^0}; \end{aligned} \quad (3.39)$$

and thus (dropping the prime on the dummy wavevector k^0 that is summed over)

$$C H C = \sum_k \epsilon_{k+Q} \epsilon_k^y = \sum_k \epsilon_{k+Q} + \sum_k \epsilon_k^y \epsilon_k; \quad (3.40)$$

For time-reversal invariant systems, $\epsilon_k = \epsilon_k^*$. Also, for our choice of Hamiltonian, $\epsilon_{k+k^0} = \epsilon_{k^0} = \epsilon_{-k^0} = \epsilon_{k^0} = 0$. Thus (3.40) simplifies to

$$CHC = \sum_k \sum_{k+k^0} c_k^\dagger c_k : \quad (3.41)$$

Since it is clear from (2.8) and (3.36) that $CHC = H$, (3.41) tells us that the dispersion relation associated with the particle-hole symmetric Hamiltonian H must satisfy the condition

$$\epsilon_{k+k^0} = \epsilon_k : \quad (3.42)$$

Next, to understand how the second condition on the chemical potential comes about, let us note the trivial fact that, since B is a reduced density matrix of ρ , for there to be any sense in talking about the manifestation of particle-hole symmetry in B , ρ must first be particle-hole symmetric, i.e. $C\rho C = \rho$. When ρ is the density matrix of the ground state at $T = 0$, then it is particle-hole symmetric whenever the ground state $|j_F\rangle$ is. For $|j_F\rangle$ to be particle-hole symmetric, it must have the transformation property

$$C|j_F\rangle = e^{i\phi} |j_F\rangle; \quad (3.43)$$

where $e^{i\phi} = 1$ is a phase factor associated with C . We know that this is satisfied only by the half-filled ground state. At finite temperature, when ρ is taken from the grand canonical ensemble and has the form given in (3.1), what, if any, extra conditions must be satisfied in order for ρ to be particle-hole symmetric?

Indeed, there appears to be cause for concern: unlike H , which is invariant under 'charge-conjugation', the fermion number operator F transforms under C as

$$CFC = \sum_i C c_i^\dagger C = \sum_i c_i c_i^\dagger = N - F; \quad (3.44)$$

and so for ρ to be particle-hole symmetric, i.e.

$$C\rho C = \rho^{-1} \exp[\beta(H - (N - F))] = \rho; \quad (3.45)$$

we must have $\beta = 0$. For a dispersion relation satisfying (3.42), $\beta = 0$ corresponds to precisely the situation of half-filling. At least for the grand canonical ensemble, there appears to be no other conditions necessary for ρ to be particle-hole symmetric.

With these conditions in mind, we may now proceed to investigate how particle-hole symmetry shows up in the pseudo-energy spectrum (and hence the spectrum of the block density matrix B). But first, we must understand how the symmetry is manifested in the Green function matrix G , and its restriction to the block, G . Knowing from our arguments above that $\beta = 0$, we see that the matrix elements of G in momentum space simplify to

$$G_{kk} = \frac{1}{\exp(\epsilon_k + 1)}; \quad (3.46)$$

Furthermore, using (3.42), we can relate $G_{k+k^0, k+k^0}$ to G_{kk} by

$$G_{k+k^0, k+k^0} = \frac{1}{\exp(\epsilon_{k+k^0} + 1)} = \frac{1}{\exp(\epsilon_k + 1)} = G_{kk}; \quad (3.47)$$

This gives rise to the condition

$$G_{ij} = \delta_{ij} - (1 - \delta_{ij}) G_{ij} \quad (3.48)$$

that must be satisfied by the matrix elements of G in coordinate space.

This same result can be derived more transparently for the special case of $T = 0$: using the fact that $C^2 = 1$, $C^\dagger = 1$, as well as (3.36) and (3.43), we find that

$$\begin{aligned} G_{ij} &= \langle j_F | c_i^\dagger c_j | j_F \rangle \\ &= \langle j_F | C (C c_i^\dagger C) (C c_j C) C | j_F \rangle \\ &= (-1)^{i+j} \langle j_F | c_i^\dagger c_j | j_F \rangle \\ &= (-1)^{i+j} G_{ij} - (-1)^{i+j} \langle j_F | c_i^\dagger c_j | j_F \rangle \\ &= -G_{ij} - (-1)^{i+j} G_{ij}; \end{aligned} \quad (3.49)$$

where we have made use of the fact that G is symmetric, i.e. $G_{ji} = G_{ij}$.

Since (3.49) is a condition satisfied by the matrix elements of G individually, it holds just as well to those restricted to the block, i.e. G_{ij} . In particular, we note that (3.49) can actually be written as a matrix equation, which when restricted to the block reads as

$$G = (1 - J)GJ; \quad (3.50)$$

where $J = \text{diag}(e^{i\phi}) = \text{diag}(1; 1; 1; 1; \dots)$ in coordinate space, and $J^2 = 1$.

To appreciate the implications of (3.50), let us consider an eigenvector $|j_1\rangle$ of G correspond to the eigenvalue λ_1 , such that

$$G|j_1\rangle = \lambda_1|j_1\rangle; \quad (3.51)$$

By (3.32), this is also the eigenvector of B , with corresponding pseudo-energy

$$\epsilon_1 = -\log \lambda_1 + \log(1 - \lambda_1); \quad (3.52)$$

Using (3.50), we find that

$$\begin{aligned} GJ|j_1\rangle &= (1 - J)GJ|j_1\rangle \\ &= J|j_1\rangle - JGJ^2|j_1\rangle \\ &= J|j_1\rangle - JG|j_1\rangle \\ &= J|j_1\rangle - \lambda_1 J|j_1\rangle \\ &= (1 - \lambda_1)J|j_1\rangle; \end{aligned} \quad (3.53)$$

i.e. the state $|j_1\rangle = J|j_1\rangle$ generated by particle-hole symmetry from $|j_1\rangle$ is also an eigenvector of G , with eigenvalue $\lambda_1 = (1 - \lambda_1)$. The pseudo-energy ϵ_1 associated with $|j_1\rangle$ is then

$$\epsilon_1 = -\log \lambda_1 + \log(1 - \lambda_1) = \epsilon_1; \quad (3.54)$$

It is interesting to note how the weights $w_{B,1,1}$, being exponentials of the pseudo-energies ϵ_1 , hide this particular aspect of particle-hole symmetry.

IV. THE $(F > 1)$ -PARTICLE SECTORS

Up to this point, our discussions have been for arbitrary dimensions. To demonstrate how the $(F > 1)$ -particle sectors can be constructed from the 0- and 1-particle sectors, we specialize to the 1-dimensional case, wherein the Fermi sea is

$$\sum_{k \in \mathcal{F}} c_k^\dagger |i\rangle = \sum_{k \in \mathcal{F}} c_k^\dagger |i\rangle; \quad (4.1)$$

where a is the lattice constant and n is the filling fraction. The 2-point functions can be computed explicitly as

$$G_{ij} = \frac{\sin \frac{n}{2} (j_i - j_j)}{j_i - j_j}; \quad (4.2)$$

We now illustrate how to construct the weights and eigenvectors of the $(F > 1)$ -particle sectors of \mathcal{B} starting from $'_0, ' _1$ and f_1 , using the example of $B = 3$ at half-filling.

At half-filling, $n = \frac{1}{2}$, the 2-point functions G_{ij} take on particularly simple values

$$G_{11} = G_{22} = G_{33} = \frac{1}{2}; \quad G_{12} = G_{23} = \frac{1}{2}; \quad G_{13} = 0; \quad (4.3)$$

with which we find, using the machinery developed in Section IIB, the 0-particle and 1-particle sectors of \mathcal{B} to be

$$\begin{aligned} {}_{3;0} &= \{ |000\rangle, |100\rangle, |010\rangle, |001\rangle \} \\ {}_{3;1} &= \{ |100\rangle, |010\rangle, |001\rangle, |101\rangle, |011\rangle, |110\rangle, |101\rangle, |011\rangle \} \end{aligned} \quad (4.4)$$

Diagonalizing these, we find

$$w_{3;0;1} = \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}; \quad (4.5a)$$

$$w_{3;1;1} = \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}; \quad (4.5b)$$

$$w_{3;1;2} = \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}; \quad (4.5b)$$

$$w_{3;1;3} = \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}; \quad (4.5b)$$

and thus

$$'_0 = \log \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8} = +3.74317 \dots; \quad (4.6a)$$

$$'_1 = \log \frac{\frac{1}{8} + \frac{1}{8}}{\frac{1}{8}} = 2.94777 \dots; \quad (4.6b)$$

$$'_2 = \log 1 = 0;$$

$$'_3 = \log \frac{\frac{1}{8} + \frac{1}{8}}{\frac{1}{8} + \frac{1}{8}} = +2.94777 \dots;$$

Since $'_1 = ' _3$, we call these a particle-hole conjugate pair of pseudo-energies, and say that $' _3$ is the particle-hole conjugate of $' _1$. The eigenvectors of the 1-particle sector are

$$f_1^y = \frac{1}{2} c_1^y + \frac{1}{2} c_2^y + \frac{1}{2} c_3^y; \quad (4.7a)$$

$$f_2^y = \frac{1}{2} c_1^y - \frac{1}{2} c_3^y; \quad (4.7b)$$

$$f_3^y = \frac{1}{2} c_1^y - \frac{1}{2} c_2^y + \frac{1}{2} c_3^y; \quad (4.7c)$$

corresponding to $' _1, ' _2$ and $' _3$ respectively.

We can easily check that the f_1^y 's obey the same anticommutator relation as the c_1^y 's, i.e. they obey Pauli's Exclusion Principle, and so the eigenvectors of the 2-particle sector of \mathcal{B} are created by

$$f_1^y f_2^y = \frac{1}{2} c_2^y c_3^y - \frac{1}{2} c_1^y c_3^y - \frac{1}{2} c_1^y c_2^y; \quad (4.8a)$$

$$f_1^y f_3^y = \frac{1}{2} c_2^y c_3^y - \frac{1}{2} c_1^y c_2^y; \quad (4.8b)$$

$$f_2^y f_3^y = \frac{1}{2} c_2^y c_3^y + \frac{1}{2} c_1^y c_3^y - \frac{1}{2} c_1^y c_2^y; \quad (4.8c)$$

with associated pseudo-energies $' _1 + ' _2 = ' _1, ' _1 + ' _3 = 0 = ' _2$ and $' _2 + ' _3 = ' _3$ respectively. Here we see that because of the particle-hole symmetry in the ground state wavefunction, the pseudo-energies of the 2-particle sector are identical to those in the 1-particle sector, which implies that the density matrix weights of the 2-particle sector are identical to those in the 1-particle sector.

For the 3-particle sector, we find that the eigenvector is created by the operator $f_1^y f_2^y f_3^y = c_1^y c_2^y c_3^y$, associated with pseudo-energy $' _1 + ' _2 + ' _3 = 0$, and hence $w_{3;3;1} = e^{0} = w_{3;0;1}$. This method of generating all $(F > 1)$ -particle sectors, starting from the 0- and 1-particle sectors, for larger block sizes at various filling fractions n was verified numerically.

Another manifestation of particle-hole symmetry is a queer degeneracy between weights in the F - and $(F + 2)$ -particle sectors. This we understand as follows: if $' _1 + \frac{1}{2}$ is a weight in the F -particle sector, then in general we can find weights $(' _1 + \frac{1}{2}) + ' _{F+1} + ' _{F+2} = (' _1 + \frac{1}{2})$ in the $(F + 2)$ -particle sector, where $' _{F+1}$ and $' _{F+2}$ are particle-hole conjugates of each other.

In fact, from the construction outlined above, we also know the pattern of degeneracy. For example, for $B = 6$ at half-filling, the pseudo-energies are of the form $' _a, ' _b, ' _c, ' _c, ' _b$ and $' _a$, corresponding to the eigenstates created by $f_a^y, f_b^y, f_c^y, f_c^y, f_b^y$ and f_a^y respectively, where $' _a > ' _b > ' _c$. We then see in the 3-particle sector that $f_b^y f_c^y f_a^y |i\rangle$ and $f_c^y f_c^y f_b^y |i\rangle$ have the same pseudo-energy of $' _b - ' _b - ' _a = ' _a = ' _c - ' _c + ' _a$, and are thus degenerate, whereas $f_c^y f_b^y f_a^y |i\rangle$ is nondegenerate with pseudo-energy $' _c - ' _b - ' _a$.

V. CONCLUSIONS

To summarize, in this paper we showed that elements of the block density matrix, $(\mathcal{B})_{b^0 b}$, can be calculated

as the expectation $\langle K_B^Y K_{B^0} \rangle$ of a product of referencing operators K_B and K_{B^0} , which are themselves formed out of fermion operators c_j and c_j^\dagger local to the block. By inspecting the matrix elements $(G_{B,1})_{ij}$ and G_{ij} of the 1-particle sector of B and the block Green function matrix G respectively for block sizes up to $B = 5$, we are led to a conjecture of the closed-form relation (2.20) between $G_{B,1}$ and G .

Adapting the technique that Chung and Peschel used to calculate the half-chain density matrix of a chain of spinless Bogoliubov fermions, we find that we can not only prove this conjecture, but also derive a closed-form relation (3.26) between the entire block density matrix B and G , which can also be written in (3.27) as the exponential of a pseudo-Hamiltonian H' . The spectrum of H' is generated by the independent fermion operators f_1^Y , which also generate the eigenvectors of G , and hence can be determined by diagonalizing G . It is amusing to numerically compute the pseudo-Hamiltonian in real space. For $n \notin \frac{1}{2}$, the generic form of H' (a bilinear in $f_{c,j}^Y$ and $f_{c,j}$) admits hopping to all other sites on the block, as well as an on-site potential. The symmetry at half-filling ensures that the on-site potential is zero and hopping only connects to the other sublattice.

We identify three important implications of (3.27) in formulating truncation schemes based on B , for the purpose of performing an RG analysis. Firstly, we note that the spectrum of B is completely determined by the block Green function matrix G . It suffices therefore to calculate the eigenvectors and eigenvalues in its 0- and 1-particle sectors. The eigenvectors and eigenvalues of the $(F > 1)$ -particle sectors of B , if needed, can be systematically generated from the fermion operators f_1^Y and their pseudo-energies ϵ'_1 , as illustrated in Section IV. This fact is evident in Ref. 14, but its significance was not emphasized. If one is studying the density matrix of a noninteracting toy model (as in this paper), we have an enormous saving in terms of computational time: instead of diagonalizing the entire B , which is of rank $O(e^B)$, we can diagonalize just the 1-particle sector $B_{:,1}$, which is of rank $O(B)$. Possible objects of such a study could be: (i) the distribution of eigenvalues;¹⁸ (ii) errors in the dispersion relation due to truncation;¹⁸ and (iii) comparing the product basis of two blocks of length B with the basis of one block of length $2B$, to weigh the effects of the correlations respectively neglected or included.

Secondly, it is highly desirable in RG calculations to ensure that the truncation scheme preserves the symmetries of the target state. Using the specific example of particle-hole symmetry, we saw in Section IV that $B_{:,F}$ and $B_{:,B-F}$ have the same set of weights, and the eigenvectors of $B_{:,F}$ are related, up to a phase, to the eigenvectors of $B_{:,B-F}$ acted upon by C . Naively, we might expect that to preserve particle-hole symmetry, all we have to do is to keep $C |j_{B,F,k}\rangle$ in $B_{:,B-F}$ if $|j_{B,F,k}\rangle$ in $B_{:,F}$ is kept. However, there is more to particle-hole symmetry. Under the action of C , the half-filled ground state $|j_F\rangle$ goes (up to a phase) back to itself. Within the block, this

global symmetry transformation brings the mixed state of the block back to the same mixed state. Because the mixed state of the block does not have a definite particle number, particle-hole symmetry is not merely a relation between $B_{:,F}$ and $B_{:,B-F}$. Rather, particle-hole symmetry imposes strict conditions on the spectra of $B_{:,F}$ and $B_{:,B-F}$, for $F; F^0 = 0; \dots; B$. In fact, in Section III F, we elaborated on the condition that particle-hole symmetry imposes on the 1-particle sector. This condition is most intuitive when written in terms of the eigenvalues ϵ_1 of G or the pseudo-energies ϵ'_1 , but not immediately apparent if we just stare at the 1-particle density matrix weights $w_{B,1,1}$. It is therefore dangerous to base symmetry-preserving truncation schemes on B and its eigenvalues alone.

This brings us to the last of the implications that we wish to highlight. While a toy noninteracting model is studied in this paper, our ultimate goal is to address interacting systems, particularly Fermi liquids. Since these (in their low-energy limit) have the same eigenstate structure as a noninteracting Fermi sea (after a unitary transformation), their density matrices also should have the same structure as a noninteracting system. The explicit form of the many-body density matrix, as exhibited in Section III of this paper, hints at the proper design of truncation schemes. Rather than independently truncating in each F -particle sector, we should define the truncated states using a set of 'creation operators' which satisfy the usual anticommutation relations, and quite likely these are closely related to the approximate quasiparticle creation operators, which should be constructed as a product of the renormalization scheme. We will have more discussions on the implications of such a truncation scheme based on picking out a set of appropriate 'creation operators' for the numerical study of interacting systems, the role of dimensionality, and comparisons with the conventional DMRG, in a second paper.¹⁸

Based on our observations on the pattern of degeneracies within and between the F -particle sectors of B in Section IV, we realize that if the truncation is carried out naively, there is a very real danger of ending up with an inconsistent scheme of truncation. This problem occurs quite generally, at various filling fractions and block sizes, but can be most clearly illustrated using our example of $B = 6$ at half-filling. For example, let us say that as the result of a naive truncation, the states $f_a^Y |j\rangle$, $f_b^Y |j\rangle$, $f_c^Y |j\rangle$ and $f_c^Y |j\rangle$ in the 1-particle sector are kept. Examining the 2-particle sector, we find the states $f_a^Y f_a^Y |j\rangle$ and $f_c^Y f_c^Y |j\rangle$, which are degenerate in their pseudo-energies. We can build up the latter, but not the former, using the 1-particle operators kept, and so we should keep the latter but not the former. If we truncate the 2-particle sector naively, then based on the density matrix weights alone we would be probably end up keeping or throwing out both of these 2-particle states.

In fact, the situation for naive truncation is worse, since the state $f_a^Y f_b^Y |j\rangle$ has lower pseudo-energy than $f_c^Y f_c^Y |j\rangle$ and will be kept instead. We see therefore that

naive truncation is likely to lead to inconsistencies: some many-particle states built up from the 1-particle states kept get thrown out, while other many-particle states that cannot be built up from the set of 1-particle states kept end up being retained. Hence, we find that as far as particle-conserving models are concerned, for any truncation scheme to be consistent, the truncation must be carried out on the 1-particle sector of B alone.

Finally, let us remark that everything done in this paper can be trivially extended to the case of spinfull fermions, so long as they are noninteracting. Every object in our calculations, in particular the Fermi sea wavefunction and the block density matrix, will merely in the spinfull case be replaced by the direct product of two such objects with spin-up and spin-down flavors.

APPENDIX A: AUTOMATING THE NUMERICAL COMPUTATION OF B

As we saw in Sec. II, each of the 2^B basis configurations of the block corresponds to an operator K_b , so that $(B)_{b'b} = \langle K_b^y | K_{b'}^y \rangle$. Therefore, to obtain all matrix elements of B it suffices to automate the calculation of expectations of an arbitrary string of creation/annihilation operators (each operator acting on one site).

First, this formal string of operators must be simplified. Through a systematic set of anticommutations, it is brought to a canonical form, such that (a) it is normal-ordered, with one substring of all creation operators followed by one substring of all annihilation operators; and (b) within each substring the operators are ordered by the site. Of course, each site can appear at most once in each substring (otherwise it reduces to zero.) A complication of this step is that the result is generally a sum of many terms in the canonical form, since every rearrangement of the form $c_1 c_1^\dagger \rightarrow 1 - c_1^\dagger c_1$ produces two terms from one.

Next, we note that within this sum, only terms containing a balanced number, say n , each of creation and annihilation operators will contribute to the expectation. By the Wick theorem, such $2n$ -point functions $G_{i_1 \dots i_n j_1 \dots j_n}$ reduces to the determinant of an $n \times n$ matrix, as shown in (2.14).

Form models in which fermion number F is conserved, we can further separate B into the various F -particle sectors B_F before diagonalization. This is particularly im-

portantly at half-filling, for there exists generic degeneracies between states in different sectors (see Section IV), and there is a danger that a naive diagonalization of the whole matrix B will produce eigenstates with mixed particle number.

The limiting consideration for the whole calculation is the diagonalization time, which is determined by the condition number of B , rather than array storage. In general, the condition number, which is the ratio of the largest weight to the smallest weight, grows exponentially with system size.¹⁸

APPENDIX B: BLOCK INVERSION FORMULA

Consider a square $N \times N$ symmetric matrix M written in matrix block form as

$$M = \begin{pmatrix} A & B \\ B^T & C \end{pmatrix}; \quad (B1)$$

where A is a square $N_1 \times N_1$ symmetric matrix, B is a $N_1 \times N_2$ non-square matrix and C is a square $N_2 \times N_2$ symmetric matrix. Here $N_1 + N_2 = N$.

If we write the inverse matrix M^{-1} also in the matrix block form

$$M^{-1} = \begin{pmatrix} D & E \\ E^T & F \end{pmatrix}; \quad (B2)$$

where D is a square $N_1 \times N_1$ symmetric matrix, E is a $N_1 \times N_2$ non-square matrix and F is a square $N_2 \times N_2$ symmetric matrix, how are D , E and F related to the matrix blocks A , B and C in M ?

Using the fact that $M M^{-1} = 1$, and thus

$$\begin{pmatrix} A & B \\ B^T & C \end{pmatrix} \begin{pmatrix} D & E \\ E^T & F \end{pmatrix} = \begin{pmatrix} 1_{N_1 \times N_1} & 0_{N_1 \times N_2} \\ 0_{N_2 \times N_1} & 1_{N_2 \times N_2} \end{pmatrix}; \quad (B3)$$

(where the subscripts, which will henceforth be dropped for notational clarity, following the 1's and 0's indicate the shape and size of the matrices) we find the following relations between the matrix blocks of M and M^{-1} :

$$AD + BE^T = 1; \quad (B4a)$$

$$AE + BF = 0; \quad (B4b)$$

$$B^T D + CE^T = 0; \quad (B4c)$$

$$B^T E + CF = 1; \quad (B4d)$$

Solving for D , E and F in terms of A , B and C , we find that

$$D = A - B C^{-1} B^T; \quad (B5a)$$

$$E = A^{-1} B - C^{-1} B^T A^{-1} B^{-1}; \quad (B5b)$$

$$F = C - B^T A^{-1} B^{-1}; \quad (B5c)$$

- ¹⁹ Ref. 14 avoid the singularities by assuming a Hamiltonian with nonzero anomalous terms containing double creation or double annihilation operators. Alternatively, realizing that we have definite occupation numbers, i.e. $\langle n_k \rangle = 0;1$ at $T = 0$, the density matrix ρ_0 must be written as a product of projection operators, i.e. $\rho_0 = \prod_{\mathbf{k} < k_F} c_{\mathbf{k}}^\dagger c_{\mathbf{k}} \prod_{\mathbf{k} > k_F} c_{\mathbf{k}} c_{\mathbf{k}}^\dagger$. This is possible only if $\tilde{n}_{\mathbf{k}\mathbf{k}} = +1$ for $\mathbf{k} < k_F$ and $\tilde{n}_{\mathbf{k}\mathbf{k}} = -1$ for $\mathbf{k} > k_F$. For the purpose of algebraic manipulations, this choice of $\tilde{n}_{\mathbf{k}\mathbf{k}}$ must be regularized, i.e. take $\tilde{n}_{\mathbf{k}\mathbf{k}} = \text{sgn}(k_F - \mathbf{k})$, and take $\epsilon \rightarrow 1$ at the end of the calculations. With this choice of regularization, ρ can then be written in terms of the zero-temperature Green function matrix G , whose matrix elements in momentum space are $G_{\mathbf{k}\mathbf{k}'} = \langle c_{\mathbf{k}}^\dagger c_{\mathbf{k}'} \rangle$ (where $\langle x \rangle = 0$ for $x < 0$ and $\langle x \rangle = 1$ when $x > 0$ is the step function) as $\rho = e^{-\ln(1+G)}$. It is then easy to show that $(1+G)^{-1} = (1+G)^{-1} 1 + [(1+G)^{-1} - (1+G)^{-1} G]$, which becomes $(1-G)$ in the limit of $\epsilon \rightarrow 1$.
- ²⁰ One possible form for the charge-conjugation operator is $C = \prod_j i^{j+1} c_j^\dagger + (-i)^{j+1} c_j$, where the product runs over all lattice sites.
- ²¹ If the bipartite lattice is not a Bravais lattice, then wherever the wavevector \mathbf{k} appears as an index, it must be replaced by the combination of \mathbf{k} and a band index. All of the results — in particular those of Section III F — still go through in this generalized case, provided that all lattice sites are symmetry equivalent.
