(June 17, 2002)

We study the low energy states of nite spin chains with isotropic (Heisenberg) and anisotropic (XY and Ising{like) antiferrom agnetic exchange interaction with uniform and non{uniform coupling constants. We show that for an odd number of sites a spin cluster qubit can be de ned in terms of the ground state doublet. This qubit is remarkably insensitive to the placement and coupling anisotropy of spins within the cluster. One{ and two{qubit quantum gates can be generated by magnetic ekls and inter{cluster exchange, and leakage during quantum gate operation is small. Spin cluster qubits inherit the long decoherence times and short gate operation times of single spins. C ontrol of single spins is hence not necessary for the realization of universal quantum gates.

03.67.Lx, 75.10.Jm

Q uantum computers outperform classical computers on certain tasks $[1\{4\}]$. The main challenge on the way to a universal quantum computer is to achieve control over single quantum mechanical two state systems (qubits) while preserving long decoherence times. Electron [5,6] and nuclear [7,8] spins have been identied as promising candidates for qubits because they are natural two state systems and decoherence times for the spin degree of freedom are unusually large [9,10].

For both electron [5] and nuclear spin [8] qubits, one{ qubit gates can be realized by local magnetic elds or by electrically tuning a single spin into resonance with an oscillating eld. Two{qubit gates rely on electrical control of the exchange interaction between neighboring electron spins. However, even for electrons in quantum dots with a typical diam eter of 50 nm, the required local control over electrical and magnetic elds is challenging. O ne possibility to circum vent the problem of either local magnetic elds [11] or local exchange interaction [12] is to encode the qubit in several spins. Such encoding has also been studied in the context of coherence{preserving qubits [13]. However, all these schem es still require control at the single{spin level.

M ore generally, the requirements on both local magnetic and electrical elds can be relaxed by increasing the size of the qubit. In the present work, we show that, for a wide class of antiferrom agnetic spin s = 1=2 chains with an odd number of sites, n_c ,

$$\hat{H} = \int_{i=1}^{n_{X}-1} f_{i}[J_{?} (\hat{s}_{i;x} \hat{s}_{i+1;x} + \hat{s}_{i;y} \hat{s}_{i+1;y}) + J_{z} \hat{s}_{i;z} \hat{s}_{i+1;z}];$$
(1)

the ground state doublet of the array [Fig.1(a)] can dene a new \spin cluster qubit" for which quantum gate operation times and decoherence rates increase only moderately with array size. These features are surprisingly stable with respect to anisotropy $(J_2 \notin J_z)$ and spatial variation (described by f_i) of the intracluster exchange, the spatial shape of the elds controlling quantum gate operation, and the cluster dimension. Spin cluster qubits can be realized in a wide variety of systems, e.g. arrays of quantum dots [5,14], clusters of P atoms in a Sim atrix [8], and electron spins in molecular magnets. In contrast to the encoded qubits suggested in earlier work [11{13}, quantum computation with spin cluster qubits is possible without control over local spin interactions.

Isotropic spin chains as qubits. { For illustration, we rst discuss a spin chain with isotropic uniform exchange, $J_2 = J_z > 0$ and f_i 1 in Eq. (1). Energy eigenstates can be labeled according to their quantum num bers of to- $\int_{i=1}^{n_c} \hat{s}_i$ and the z {com ponent of total spin, talspin Ŝ = \hat{S}_z . Because of the antiferrom agnetic exchange, states in which the total spin of the chain ism in in ized are energetically most favorable [15]. For odd n_c, the ground state is a S = 1=2 doublet separated from the next excited state $J^{2}=2n_{c}$ determ ined by the lower bound by a gap of the des C loiseaux-Pearson spectrum. W e de ne the spin cluster qubit in terms of the S = 1=2 ground state doublet by $\hat{S}_z \hat{D}i = (\sim = 2) \hat{D}i$ and $\hat{S}_z \hat{J}i =$ (~=2)jli.The states fjli; jlig do not, in general, have a simple representation in the single spin product basis, but rather are superpositions of $n_c \models [(n_c - 1)=2]! [(n_c + 1)=2]!$ states [Fig. 1 (b)]. For example, for the simplest nontrivial spin cluster qubit with $n_c = 3$,

$$jDi = \frac{2}{p-1}j"i_1j#i_2j"i_3 \qquad \frac{1}{p-1}j"i_1j"i_2j#i_3 \qquad \frac{1}{p-1}j#i_1j"i_2j"i_3; \qquad (2)$$

and jli is obtained by ipping all spins.

In spite of their complicated representation in the single{spin product basis, j) and jliare in many respects

very sim ilar to the states j"i and j#i of a single spin and, hence, can be used as qubit states for universal quantum com puting [5]. Because fjDi; jlig belong to one S = 1=2 doublet such that \hat{S} $\mathcal{D}i = \sim \mathcal{J}i$, and $\hat{S}^+ \mathcal{J}i = \sim \mathcal{D}i$ where $\hat{S} = \hat{S}_x$ $\hat{\mathbf{s}}_{v}$, a magnetic eld B constant over the cluster acts on the spin cluster qubit in the same way as on a single-spin qubit. Hence, both the one{qubit phase shift and the one {qubit rotation gate can be generated by magnetic elds B_z (t) and B_x (t), respectively, possibly in combination with g factor engineering [5,16]. For a given $B_{z;x}$ (t), operation times of one {qubit gates are equal to the ones for the single-spin qubit. We note that, due to quantum mechanical selection rules, we have hiĵji = hiĵji = 0 for ji 6 ji; ji, ie., a uniform magnetic eld does not cause leakage to states outside the ground state doublet.

For the CNOT gate, one requires a tunable exchange interaction \hat{H} between one or several spins of neighboring spin cluster qubits I and II. For simplicity, we rst restrict our attention to an isotropic exchange coupling $\hat{H} = J$ (t) $\hat{s}_{n_c}^{I}$ \hat{s}_{1}^{II} between the outerm ost spins of clusters I and II, respectively [Fig. 1 (c)]. This exchange interaction will in general not only couple states within the two{qubit basis fj0i; j1i; j10i; j11ig, but will also lead to transitions to excited states (leakage). If J (t) changes adiabatically, i.e., on time scales long compared to ~= and jJ (t)j for all times t, leakage remains sm all (see below). The action of \hat{H} can then be described by an elective H am iltonian in the two{qubit product basis

$$\hat{H} = J_{z}(t)\hat{S}_{z}^{T}\hat{S}_{z}^{T} + \frac{J_{?}(t)}{2}(\hat{S}^{T}\hat{S}^{T} + \hat{S}^{T}\hat{S}^{T}); \quad (3)$$

where the rom an numbers label the spin clusters, J_z(t) = 4J (t) jh0 $\beta_{n_c;z}^{I}$ $\beta_{i_1j_1}$ $\beta_{i_1z}^{II}$ $\beta_{i_1I_1}$ $\beta_{i_1I_2}$ $\beta_{i_1I_1}$ $\beta_{i_1I_2}$ $\beta_{i_1I_1}$ $\beta_{i_1I_2}$ $\beta_{$

A lthough we have so far discussed one{qubit gate operations induced from spatially uniform magnetic eds, such uniform ity may be dicult to achieve experimentally. One{qubit gates can be performed with spatially varying eds B_{ixx} and B_{izz} (or g factors) for which $\mathfrak{flj}_{i=1}^{n_c} \mathfrak{g}_i \ \mathsf{BB}_{ixx} \mathfrak{S}_{ixx} \mathfrak{flj} \notin 0$ and h0j $\prod_{i=1}^{n_c} \mathfrak{g}_i \ \mathsf{BB}_{izz} \mathfrak{S}_{izz} \mathfrak{fli} \notin 0$, respectively. Similarly, the analysis leading to Eq. (3) remains valid for a wide class of coupling H am iltonians $\hat{\mathsf{H}}$ for which $\mathfrak{hl0}\mathfrak{fl} \mathfrak{flli} \notin 0$. For illustration we discuss two examples. First, couplings between several spins of cluster I to several spins of cluster II, such as $\hat{\mathsf{H}} = J = \prod_{i=1}^{n_c} \mathfrak{S}_i^{\mathrm{II}} \mathfrak{S}_i^{\mathrm{II}}$, are permitted and

even lead to a decrease of $_{\mathbb{C}\,\mathbb{N}}$ because the coupling of several spins in the m icroscopic H am iltonian leads to an increased e ective coupling between the clusters. Second, a modi cation of the intracluster exchange couplings by \hat{H} due to additional terms such as J \hat{S}_1^{II} \hat{S}_2^{II} does not invalidate the proposed gate operation scheme. This illustrates the most signi cant advantage of the spin cluster qubits over single-spin qubits { that it is su cient to control magnetic ebds and exchange interactions on a scale of the spin cluster diam eter. For the linear spin cluster qubit, this length scale is n_c times larger than the original qubit.

A set of universal quantum gates is necessary but not su cient for the realization of a quantum computer. Rather, additional requirements must be met, including initialization, decoherence times large compared to gate operation times, and readout [17]. Initialization can be achieved by cooling in a magnetic eld B_z to a temperature [5] T . g $_{\rm B}$ B_z=k_B < =k_B. Because the state of the spin cluster qubit, jDi or jLi, determines the sign of the local magnetization at each site within the spin chain [Fig. 1(b)], readout of the spin cluster qubit can be accomplished by readout of the spins within the cluster [5,18].

An important consideration is the elect of decoherence on spin cluster qubits. The scaling of the decoherence rate with system size depends on the microscopic decoherence mechanism. For electron spins in quantum dots, uctuating elds and nuclear spins have been identied as dominant sources [5,6,19]. We model [5] the action of uctuating magnetic elds by $\hat{H}^B = b(t)\hat{S}_z$ where b(t)is G aussian white noise, $hb(t)b(0)i = 2^{-B}$ (t). Because the magnetic moment $g_B = 2$ of the spin cluster qubit is the same as for a single spin, the decoherence rate [20]

 $^{\rm B}$ is independent of $n_{\rm c}$. In contrast, the decoherence rate due to uctuating elds acting independently on each site increases linearly with $n_{\rm c}$.

Spin dynam ics during gate operation. { O ne{ and two{ qubit gates induce spin dynam ics in the clusters, and leakage out of the ground state doublet is required to remain small. In order to quantify leakage, by num erical integration of the Schrödinger equation we trace the time evolution of a small spin cluster qubit ($n_c = 5$) during the one{qubit rotation gate. The qubit is rotated coherently from jDi into jLi, which corresponds to a simultaneous rotation of all spins Figs. 2(a) and (b)]. The one{qubit rotation can also be generated by an inhom ogeneous eld B_x acting, e.g., only on the central spin of the cluster as long as $g_B B_x$ [Figs. 2(a) and (b)]. Leakage due to instantaneous switching is less than 0.3% for $g_B B_x = 0.1J$, but increases with $g_B B_x$ [Fig. 2(b)].

For the special cases $J_z = J_2$ and $J_z = 0$ in Eq. (3), an explicit pulse sequence for the CNOT gate has been derived previously in Refs. [5,21]. We dene the unitary time evolution operator U (=2) =

T exp $i dt \hat{H} = v$, with $dt J_{?}(t) = v = = 2$. Then, m ore generally,

$$U_{CNOT} = e^{i S_{y}^{II}=2} e^{i2 n_{1} \frac{3}{5}=3} e^{i2 n_{2} \frac{3}{5}I=3} U (=2)$$
$$e^{i S_{y}^{I}} U (=2) e^{i S_{x}^{I}=2} e^{i S_{x}^{II}=2} e^{i S_{y}^{II}=2} (4)$$

is the CNOT gate for an arbitrary elective XXZ { coupling Hamiltonian [Eq. (3)] if $J_{p_1^2} \neq 0$, where $n_1 = (1; 1; 1) = 3$ and $n_2 = (1; 1; 1) = 3$. We can med that for the complete pulse sequence the dynamics of two spin clusters is as predicted on the basis of the twolevel description [Fig. 3]. Leakage induced by \hat{H} is small for J because all spins in the clusters corotate although \hat{H} couples only the outerm ost spins.

Spatially varying and anisotropic exchange. { We show next that spin cluster qubits are extremely robust with respect to spatial variation (accounted for by f_i in Eq. (1)) and anisotropies $(J_2 \in J_z)$ of the intracluster exchange. For spatially varying isotropic exchange $(J_2 = J_z = J)$, the system still exhibits a S = 1=2 ground state doublet [15] and the above analysis remains valid. In system s such as quantum dot arrays where it is possible to engineer the intracluster exchange Jf_i during sample growth, the qubit basis states fjli; jlig can be tailored to some extent.

We next consider the XY chain, $J_z = 0$. By the Jordan {W igner transform ation [22], the XY spin chain is mapped onto a system of noninteracting spinless ferm ions with spatially varying hopping am plitudes, $\hat{H} = (J_2 = 2) \prod_{i=1}^{n_c - 1} f_i (\stackrel{y}{_{i+1}} \stackrel{,}{_i} + \stackrel{y}{_{i+1}})$, where $\hat{}_i$ annihilates a Jordan-W igner ferm ion at site i. We is not that the one{particle H am iltonian has $(n_c - 1)=2$ states with negative and positive energy, respectively, which are pairw ise related to each other by staggering of the wave function. There is one zero{energy eigenstate

$$\mathbf{e}_{0} / \mathbf{1}; \mathbf{0}; \quad \frac{\mathbf{f}_{1}}{\mathbf{f}_{2}}; \mathbf{0}; \frac{\mathbf{f}_{1}\mathbf{f}_{3}}{\mathbf{f}_{2}\mathbf{f}_{4}}; \mathbf{0}; \dots; \quad \frac{\mathbf{f}_{1}\mathbf{f}_{3} \dots \mathbf{f}_{n_{c}}}{\mathbf{f}_{2}\mathbf{f}_{4} \dots \mathbf{f}_{n_{c}}} \quad : \quad (5)$$

The ground state doublet of the XY chain corresponds to the lowest $(n_c = 1)=2$ and $(n_c + 1)=2$ Jordan {W igner ferm ion levels lled. For f_i 1, ' $J_2 = n_c$. Sim ilarly to the spin chain with isotropic exchange, one { qubit gates can be realized by magnetic elds B_z (t) and B_x (t) unless $h_{1}\hat{s}_{x}\hat{D}i = 0$. For n_{c} 9 and fi 1, j1\$_xjDij 0:4. From Eq. (5), one can also calculate all matrix elements entering Eq. (3). In particular, for $f_i = 1$, h0 $f_{h_c,z}$ Di = $1=(n_c+1)$, and $\frac{1}{2}n_c$, $\frac{1}{2}$ $\frac{1$ of the anisotropy of the intrachain exchange, \hat{H} (which is isotropic in the single spin operators) translates into an anisotropic e ective Hamiltonian Eq. (3). Nevertheless, the CNOT gate can still be realized according to Eq. (4). For the anisotropic chain, a magnetic eld applied along an axis n translates into a rotation around the axis / $(2 \ln \hat{f}_x \text{Dip}_x; 2 \ln \hat{f}_x \text{Dip}_y; n_z)$

in the Hilbert space spanned by fjli; jlig. A one{ qubit rotation around an arbitrary axis hence requires appropriate rescaling of B. For example, the rotation corresponding to exp(i2 n₁ $\frac{1}{5}$ -3) [Eq. (4)] for the isotropic chain can be achieved by applying a magnetic eld B = B₀(1 + 2=(2)1 \hat{s}_x $\hat{p}ij^2$)¹⁼² $\frac{1}{3}$ along the axis / (1; 1;2)1 \hat{s}_x $\hat{p}ij$ for a time 2 ~=3g _BB₀. For given J and B, the CNOT gate operation time increases at m ost linearly with n_c.

For J_z J2 (Ising{ like system s), where $\mathfrak{Di} = \mathsf{j}"i_1 \mathsf{j} \# i_2 ::: \mathsf{j}"i_n$ + 0 (J₂ =J₂), the ground state doublet is separated from the next excited state by an n_c{independent $J_z m in(f_i)$. In perturbation theory in $J_2 = J_z$, for f_1 1, the matrix elements $(2J_2 = J_z)^{(n_c - 1)=2}$ decrease exjuljî_x Dij juljî_{n x} Dij ponentially with nc. Even form edium sized chainsnc & 9 and $J_2 = J_z < 0.2$, an isotropic H translates into an effective Ising Hamiltonian, J ? ' 0 in Eq. (3). Hence, only quantum computing schemes which rely on Ising interactions [23] are feasible.

Discussion. { The main idea of the present work applies not only to spin chains but remains valid for a wide class of antiferrom agnetic system s with uncom pensated sublattices, also in higher dimensions d > 1 and for larger spins s > 1=2. W e illustrate the advantages of spin cluster qubits for electron spins in quantum dots with a typical diam eter of d = 50 nm, where the exchange coupling can be as large as 10 K [6]. O ne{qubit operations are realized, e.g., by g{factor engineering in presence of a static eld B ' 1 T.W e now com pare the performance of a spin cluster qubit formed by $n_c = 5$ quantum dots coupled by an intracluster exchange J = 10 Kwith a single spin qubit. To obtain an estimate, we consider gate operation by switching the magnetic eld B to $g_B B = 0.7 \text{ K}$, and J = 2.3 K [6], sm all compared to the energy gap = 72 K of the spin cluster. For single spins, the gate operation times for the NOT and CNOT gate are 36 ps and 117 ps, respectively. A ssum ing that the magnetic eld decreases smoothly from its maximum value at the central spin of the spin cluster qubit to 0:2B acting on spins 2 and 4, we nd that the operation time for one {qubit gates increases by a factor $1=2 \ln \beta_{3,x} + 0.2 \delta_{2,x} + 0.2 \delta_{4,x}$ Dij = 2.2 com pared to the single spin. Sim ilarly, for the operation time of the CNOT gate we nd 280 ps for the spin cluster qubit. The main advantage of the spin cluster qubit is that it is sufcient to controlm agnetic elds or g factors on a length scale $ofn_cd = 250$ nm and exchange couplings on a scale of $2n_c d = 500 \text{ nm}$. This would allow one to control the exchange between neighboring clusters optically [14] at the expense of an increase in gate operation times by a factor of 2.

O ther possible applications for spin cluster qubits include, e.g., P atoms in a Simatrix [8] and molecular magnetic systems [24]. For electron spins of P atoms in a Simatrix, the requirement of positioning P with lattice spacing precision [8,25] can be circum vented by the use of spin clusters instead of single spins. More generally, the present work shows that for universal quantum gates control is not required at the level of single electron spins. Because a qubit can always be mapped onto a spin 1=2, the general principle of arranging several qubits into a cluster qubit applies to any quantum computing proposal.
