We have investigated a single crystal of CeAgSb₂ using low field ac-susceptibility, thermal expansion and magnetostriction measurements. The thermal expansion coefficient α , exhibits highly anisotropic behaviour between 3K and 80K: α (for $\Delta L/L \perp c$) exhibits a sharp peak at T_N followed by a broad maximum at 20K, while a sharp negative peak at T_N followed by a minimum at 20K has been observed for ($\Delta L/L \parallel$) the c direction. The observed maximum and minimum in $\alpha(T)$ at 20K have been attributed to the crystalline field effect (CEF). The magnetostriction (MS) also exhibits anisotropic behaviour with a large MS along the c -axis.

Recent studies on RAgSb₂ (R=rare earth) compounds have shown that these compounds crystallize in the tetragonal ZrCuSi₂ type structure [1-6]. Among these compounds, CeAgSb₂ is the most interesting. The resistivity and thermoelectric power of CeAgSb₂ show a typical Kondo lattice behaviour [1]. The magnetization exhibits strongly anisotropic behaviour with the easy c -axis of magnetization in the magnetic ordered state (probably a complex antiferromagnetic (AFM) state with a FM component) below 10K, while in the paramagnetic state there is an easy ab -plane [1,5]. The magnetization isotherm at 2K shows that the easy magnetization direction changes from the c -axis to the ab -plane above 1T field with the saturated moment $\mu^{sat}=1.1\mu_B/\text{Ce-ion}$ for $B \perp c$ and $0.37\mu_B/\text{Ce-ion}$ for $B \parallel c$ at 5.5T field. The neutron diffraction measurements at 2K show the presence of only a single magnetic Bragg peak, (1 0 1), with moment of $0.33\mu_B/\text{Ce-ion}$ [5]. The zero-field μSR study shows well-defined frequency oscillations

with an anomalously low internal field of 53mT at the muon site, which is in agreement with the extremely low frequency (0.25MG) observed in a Shubnikov-de Haas study [4, 6].

In the present work we have investigated a single crystal of CeAgSb₂ using ac-susceptibility (χ_{ac}), thermal expansion, and magnetostriction measurements with the aim of throwing more light on the complex electronic and magnetic ground state. The single crystal of CeAgSb₂ was grown in an evacuated BN-crucible at 1350°C by the Bridgmann method. The inductive component, $\chi'_{ac}(T)$ of the ac-susceptibility of CeAgSb₂ single crystal with $B_{ac}(5G)\parallel c$, exhibits a sharp peak at 9.7K which is due to the magnetic ordering of the Ce-moments (inset of Fig.1). $\chi'_{ac}(T)$ for $B_{ac}\perp c$ also exhibits a similar peak, but the peak height is only 27% of $B_{ac}\parallel c$. The c-axis is therefore the easy magnetization direction at low temperature, which is in agreement with the dc magnetization study [4]. It would be interesting to compare the $\chi'_{ac}(T)$ signal of CeAgSb₂ with that from the ferromagnetic CePdSb [7]. Well below T_N (or T_C) $\chi'_{ac}(T)$ of CeAgSb₂ is very small, while that of CePdSb retains about 92% of its peak value. This again implies that the magnetic ground state of CeAgSb₂ is more complicated than that of a simple AFM or FM.

Fig.1 shows the linear thermal expansion ($TE=\Delta L/L$) as a function of temperature for CeAgSb₂ single crystal parallel to c-axis ($TE\parallel c$) and perpendicular to c-axis ($TE\perp c$) along with the isostructural nonmagnetic reference polycrystalline LaAgSb₂. $\Delta L/L$ of LaAgSb₂ exhibits a typical behaviour expected for the thermally excited phonons. On the other hand, $\Delta L/L$ of CeAgSb₂ shows highly anisotropic behaviour, positive for $TE\perp c$ and negative for $TE\parallel c$, with a sudden change at T_N in both the directions. The magnetic contribution to the thermal expansion coefficient, $\alpha_M(T)$ of CeAgSb₂ along both the directions was estimated by subtracting $\alpha(T)$ of LaAgSb₂. $\alpha_M(T)$ exhibits a sharp peak and a broad peak at T_N and 20K, positive for $TE\perp c$ and negative for $TE\parallel c$, respectively. It should be noted that the $\alpha_M(T)$ of polycrystalline CeAgSb₂ also shows a broad peak at 18K, but no clear peak at T_N [3]. The absence of the peak at T_N in the polycrystalline sample might be due to the cancellation of positive (for $TE\perp c$) and negative (for $TE\parallel c$) contributions observed in the single crystal. The sharp peak at T_N in CeAgSb₂ single crystal arises due to the development of anisotropic spin-spin correlations because of the magnetic ordering of Ce-moments. On the other hand the broad peak (maximum and minimum) at 20K in both the directions has been attributed to the CEF effect on the $J=5/2$ state of the Ce³⁺ ion. This is consistent with our recent high resolution inelastic neutron scattering measurements on CeAgSb₂, which show two well defined crystal field excitations, at 5.1meV and 12.4meV, as expected for the tetragonal point symmetry of the Ce ion [8]. It is interesting

to note that the observed anisotropic behaviour of $\alpha_M(T)$ of CeAgSb₂ is very similar to that observed for CeRhIn₅ single crystal, which also has the tetragonal crystal structure [9]. The calculated $\alpha_M(T)$ for CeRhIn₅ on the basis of the CEF model exhibits a maximum and minimum around 25K for [100] and [001] directions, respectively [9]. In order to investigate the effect of magnetic field on the $\alpha_M(T)$ of CeAgSb₂, we have measured $\alpha_M(T)$ in an applied magnetic field of 8T (Fig.2). The observed sharp peak at T_N in zero field was almost suppressed in 8T field for both the directions.

We estimated the value of $dT_N/dP = -0.088$ (K/kbar), using the Ehrenfest relation and the heat capacity data from Ref.[2], which is in good agreement with the experimentally measured value of -0.095 (K/kbar) on the polycrystalline CeAgSb₂ [3]. The negative sign of dT_N/dP indicates that CeAgSb₂ is on the right-hand side of the Doniach phase diagram [3].

Fig.3 shows the magnetostriction (MS) isotherms measured at various temperatures for $(\Delta L/L)_{\parallel c}$ and $(\Delta L/L)_{\perp c}$ with applied fields $B_{\parallel c}$ and $B_{\perp c}$ directions. MS exhibits highly anisotropic behaviour with the largest length change for $(\Delta L/L)_{\parallel c}$. Between 14K and 20K MS exhibits a quadratic behaviour, for all measured directions (Figs.3a-d), which could be understood on the basis of the free energy of the system in an applied field. An interesting behaviour of MS is observed for $(\Delta L/L)_{\perp c}$ and $B_{\perp c}$ geometry at low temperatures (Fig.3d). At 3K MS exhibits a peak at 3.3T, which is consistent with the observed peak in the magnetoresistance measurements and has been attributed to the field induced transition to the easy ab-plane of magnetization [4]. Furthermore, with increasing temperature from 3K, the position of the peak moves to a lower field, which indicates that the smaller critical field for the field induced transition. A small hysteresis in MS was observed at 3K suggesting the presence of a FM component. This result along with the absence of the domain walls contribution at low fields in MS of CeAgSb₂ indicates that the magnetic ground state is not a simple FM, but a complex AFM.

In conclusion, thermal expansion and magnetostriction measurements of CeAgSb₂ single crystal exhibit highly anisotropic behaviour. These results indicate that the anisotropic magnetic exchange and CEF-anisotropy are playing an important role.
