In deposition with a poisoning species, we show that the transition to a blocked or pinned phase may be viewed as an absorbing transition in the directed percolation (DP) class. We consider a ballistic-like deposition model with an active and an inactive species that represents its basic features and exhibits a transition from a growing phase to a blocked or pinned phase, with the deposition rate as the order parameter. In the growing phase, the interface width shows a crossover from the critical W t behavior to K ardar-Parisi-Zhang (KPZ) scaling, which involves DP and KPZ exponents in the saturation regime. In the pinned phase, the maximum heights and widths scale as H $_{\rm S}$ W $_{\rm S}$ (p $\rm p_{c}$) $^{\rm k}$. The robustness of the DP class suggests investigations in real system s.

During som e deposition processes, the presence of different chem ical species in proves Im s' properties but m ay also lead to undesired features, such as the decrease of grow th rates due to erosion processes or the saturation of dangling bonds at the surface. One im portant exam ple is the deposition of Si lms doped with P by CVD or M BE in atm ospheres with phosphine [1{3], in which it is observed the decrease of growth rates when phosphine ux increases. This feature seems to be related to the saturation of dangling bonds at the surface [3]. Similar poisoning e ect appears in diam ond CVD in atmospheres with boron and nitrogen [4]. High uxes of the poisoning species may cancel out the growth of the main species, thus showing a transition from a growing phase to a blocked or pinned phase. Here we will argue that, in the absence of erosion processes of these two species, it may be viewed as a transition to an absorbing state in the directed percolation (DP) class [5{8], and we will present a deposition model that represents the main features of this process.

W e will consider a statisticalm odel that represents the essential aspects of lm s' grow th and m ay be used to calculate grow th rates, analyse surface roughness scaling and predict a dynam ic transition. It is a ballistic-like deposition model with two species, an active one (A) and an inactive one (B), with a continuous transition from a growth phase to a blocked phase. The mapping of this transition onto the DP class shows that the growth velocity is the order parameter of the problem and that the growth phase corresponds to the active phase of DP. Thus their physical properties are completely di erent from previous models of surface grow th with pinning or roughening transitions [9{13]. The observed fall of deposition rates in the grow th regim e agrees qualitatively with deposition experiments showing poisoning e ects. Thus, the interpretation of the pinning process as a transition to an absorbing state and the robustness of the DP class strongly suggest that other transitions to blocked phases due to poisoning of lm s' grow thare also in the DP class. Furtherm ore, we will show that the scaling of quantities such as growth rates, surface roughness and thicknesses of blocked deposits involve the exponents of the K ardar-Parisi-Zhang (K P Z) theory [14] and D P exponents, and m ay eventually be used to compare our theory with experimental data.

In the follow ing we will describe our model, show the results in one-dimensional substrates while discussing the relation to DP, show some results in two dimensions and present a naldiscussion.

In our model, particles A and B are released from random positions above a d-dimensional surface of length L with probabilities 1 p and p, respectively. The incident particle follows a straight vertical trajectory towards the surface. Aggregation is allowed only if the incident particle encounters a particle A at the top of the colum n of incidence or at the top of a higher neighboring colum n. O therw ise the aggregation attempt is rejected. Fig. 1a illustrates the aggregation rules. A colum n in which aggregation is possible will be called an active colum n. The deposition time is the number of deposition attempts per substrate colum n, thus the deposition rate (number of deposited particles per unit time) is equal to the fraction of active colum ns.

It is clear from Fig. 1a that particles B represent in – purities that prevent the grow th to occur in their neighborhoods. This model resembles the AC model proposed by other authors [15,16], but their results are very dierent from ours (a morphological transition was suggested in d = 2 [16], but it was not quantitatively studied). Our ndings are also completely dierent from the two-species RSOS model of Ref. [17], although the pure case (p = 0) also obeyed K P Z scaling.

Now we will present results in d = 1.

For small values of p, the growth process continues inde nitely, such as in the pure model (p = 0) However, when p increases, the growth rate r decreases due to the increase in the density of B at the surface, as shown in Fig. 2a. In Fig. 2b we show lnr versus ln (p_c p) for $p_c=0.20715$, which gives the best linear t of the data for 0.19 . Thus we obtain

r ; p p; (1)

 $w \pm p_c = 0.20715$ 0.00010 and = 0.282 0.012.

The instantaneous grow th rate decays as the density of particles A at the surface. Focusing on the surface con guration, we notice that the growth rules of Fig. 1a may be mapped onto a d-dimensional contact process [18,7] (CP) in which a top A represents a particle and a top B represents a hole (or empty site), as shown in Fig. 1b. W hen the deposition of a B occurs in a column with a top A, it corresponds to the annihilation of a particle in the CP. On the other hand, the deposition of an A in a column with a top B and a neighboring column with a top A corresponds to o spring production in the CP. Notice that the stability of the absorbing state is represented by process 4 in Fig. 1b. The probabilities of annihilation and o spring production in the CP are not trivially related to p, since they also depend on the neighboging heights' distribution.

The equivalence to a CP indicates that the transition is in the DP class, with the density of top A or the growth rate r as the order parameter. The above value of the exponent and forward results support this statement (the best known estimate for DP is = 0.276486 0.000008 [19]).

Here it is relevant to recall that all known statistical models showing continuous transitions to absorbing states, with positive one-component order parameters, short-range interactions and no additional symmetries, are in the DP class [8,20]. This so called robustness of the DP class is the reason for us to expect universality in real system s' transitions with the same blocking mechanisms of our model.

At the critical point in d = 1 and L 8192, we estimated the deposition rate at very long times, r_1 (L), and obtained

$$r_{c} (L; t=1) L;$$
 (2)

with = 0.26 0.02. This result is consistent with the expected D P value = = $_{?}$ (the best known estimate $_{?}$ = 1.096854 0.000004 [19] gives 0.252). We also estimated r for relatively short times in very large substrates (L = 65536), and obtained

$$r_{c} (L = 1;t) t;$$
 (3)

with = 0:160 0:005.This estimate also supports the DP equivalence, which gives = $=_k$, where $_k$ is the parallel correlation length exponent (best known estimate $_k = 1:733847$ 0:000006 [19]).

The interface width, de ned as

$$W (L;t) = \frac{1}{L^{d}} X + \#_{1=2} + \frac{1}{L^{d}} X + \frac{1}{L^{$$

obeys dynam ic scaling involving exponents of D P and K P Z theory (overbars and angular brackets in Eq. 3 denote spatial and con gurational averages, respectively). In order to understand its behavior below the critical point, we rst show the results at p_c and very large substrates in Fig. 3. The interface width W increases as

$$W \quad t; p = p; \qquad (5)$$

as a consequence of the nite fraction of growing columns in isolated branches and the increasing fraction of blocked columns, which give rise to increasingly large heights' di erences.

The evolution of the interface width for $p^{<}$ p_{c} is presented in Fig. 4, where we plotted $ln\,W$ as a function of the scaling variable x t $^{\times}$, with $_{k}$ = 1:733847 [19], in substrates with L = 4096. There is a transient region for t < t_{cros} $^{\times}$, in which W shows the rapid increase typical of the critical point (Eq. 5). Notice that t_{cros} is the characteristic time of correlations in the D P process. Att t_{cros},W crosses over to a K P Z scaling

$$W t^{\kappa}$$
 (6)

with $_{\rm K}$ = 1=3 in d = 1. Finite-size e ects are responsible for the reduced declivities in Fig. 4 when compared to the asymptotic forms of Eqs. (5) and (6) (strong nite-size e ects are typical of ballistic deposition models [21]).

For long times, nite-size e ects lead to the saturation of the interface width. The extrapolation of data for several p and L, also considering nite-size e ects [21], leads to

$$W_{sat}$$
 L^K; 1;L 1; (7)

with the K P Z exponent $_{\rm K}$ = 1=2 and the D P exponent. is the typical lateral distance between active columns, but appears in Eq. (4) as a vertical scaling length, accounting for lateral correlations in the roughness saturation regime. The divergence of W _{sat} at p_c indicates the failure of K P Z scaling at criticality.

For $p > p_c$, the growth process stops when the whole surface is covered with B, for any length L. The heights of the blocked deposits attain limiting or saturation values with average H_s, and the interface widths attain saturation values W_s (W_s should not be confused with W_{sat} for $p < p_c$, since the form eriss property of in nitely large static deposits and the latter is related to nite-size effects in growing deposits). The time for surface blocking is the characteristic time of survival of particles in the corresponding CP, consequently H_s and W_s should be have as the parallel correlation length in the absorbing phase:

$$H_s W_s$$
 ()^k: (8)

Eq. (8) is con med in Fig.5, where we show linear ts of $\ln H_s$ and $\ln W_s$ versus log (), with p = 0.20715 (the same estimate of the growing phase). From ts with

di erent values of p_c we obtain $_k = 1.75$ 0.05, which is also consistent with D P within error bars [19].

A nalogous results were obtained in two-dimensional substrates. In Fig. 6a we show logr versus log , with $p_c = 0.4902$, which gives $= 0.573 \quad 0.020$ (Eq. 3). In Fig. 6b we show hW versus lnx, x t *, for several values of p, considering $_k = 1.295$ [22]. Again it shows exponents consistent with DP and the crossover from DP to KPZ scaling. At $p = p_c$ we obtained Eq. (5) with 0.46, to be compared with the DP value

0:451 [22]. The results in d = 2 are less accurate due to the limitations in lattice lengths (L 256), but are essential to justify any comparison of our theory with experiments.

The applicability of ourm odel to real grow th processes is lim itted due to the ballistic aggregation conditions, the absence of di usion m echanism s etc. H ow ever, if poisoning e ects lead to a transition to a blocked phase and if it can be interpreted as a transition to an absorbing phase, then the robustness of the D P class [20,8] suggests this type of transition. A possible realization is Sideposition in atm ospheres with phosphine (PH $_3$), which shows a decrease of grow th rate with increasing phosphine ux. The saturation of phosphorous dangling bonds by hydrogen at the surface was suggested as the main blocking mechanism [3], but to our know ledge no blocking transition was found yet. Another possible application is diam ond CVD in atm ospheres with boron, in which the formation of an amorphous BCN phase blocks the growth of the diam ond phase for boron to carbon ratios above B = C = 0:1 [4]. It seems to be an absorbing transition sim ilar to our model and, consequently, is a candidate to the DP class.

Finally, it is important to recall the di erences between the transition found in our model and the pinning transitions by directed percolation of growing interfaces in disordered media [9,10,23,8]. In that case the interface is blocked if the impurity concentration exceeds the D P threshold, then in nite surface growth is found in the absorbing phase of the impurities system. Consequently, the critical behavior of geometric quantities such as growth rate and interface width are completely di erent; for instance, Eq. (3) is obeyed with $= \frac{2}{10}$ [23]. A very di erent correspondence to D P is also found in models with competition between aggregation and desorption that show roughening transitions [11], in which the lm growth regime parallels the absorbing D P phase.

ACKNOW LEDGMENTS

FIG.1. (a) Examples of deposition attempts in d = 1, in which only the congurations of the incident column and of neighboring columns are shown. Open squares represent particles A, lled squares represent particles B and crossed squares represent incident particles (A or B). In processes (1), (2) and (3), aggregation occurs at the positions marked with a lled circle. In processes (4) and (5) the aggregation attempt is rejected. Notice that, in processes (3) and (4), lateral aggregation to the right is not possible because the neighboring A is not at the top of the column. (b) The equivalent one-dimensional contact process, in which a top A corresponds to a particle (empty circles) and a top B corresponds to a hole (underlined empty site). The initial conguration and the possible nal congurations (for the cases of incident A or incident B) are shown.

FIG.2. (a) Deposition rate r versus probability p of incidence of particles B, in d = 1. (b) Scaling of r near $p_{\rm c}$ = 0.20715.

FIG.3. Time evolution of the interface width W at the critical point $p_{\rm c}$ = 0.20715 in d = 1, for a very large substrate (L = 65536).

FIG. 4. In (W) versus In (x), with the scaling variable x t *. From below to above, p = 0.15, p = 0.17 and p = 0.18 (L = 4096). The regions of critical DP and KPZ behaviors are indicated.

FIG.5. Saturation height ln (H $_{\rm s})$ (squares) and saturation width ln (W $_{\rm s})$ (crosses) versus ln $\,$ in d = 1, with $p_{\rm c}$ = 0.20715. The solid line is a least squares t of H $_{\rm s}$ data, giving a declivity $_{\rm k}$ 1:75.

FIG. 6. (a) Scaling of the deposition rate r near $p_c = 0.4902$ in d = 2, giving = 0.573. (b) ln (W) versus ln (x), with x t^k, for p = 0.44, p = 0.46 and p = 0.47 from below to above (L = 256).
