# $P$ atterns in random ly evolving netw orks: Idiotypic netw orks 

M. B rede and U. B ehn<br>Institut fur Theoretische Physik, U niversitat Leipzig, A ugustusplatz 10, D-04109 Leipzig, G erm any (D raft, A pril 14, 2024)

#### Abstract

W e present a m odel for the evolution of netw orks of occupied sites on undirected regular graphs. At every iteration step in a parallel update I random ly chosen em pty sites are occupied and occupied sites having degree outside of a given interval ( $t_{1} ; t_{u}$ ) are set em pty. D epending on the in ux $I$ and the values of both low er threshold and upper threshold of the degree di erent kinds of behaviour can be observed. In certain regim es stable long-living pattems appear. W e distinguish tw o types of pattem: static pattems arising on graphsw ith low connectivity and dynam ic pattems found on high connectivity graphs. Increasing I pattems becom e unstable and transitions betw een alm ost stable pattems, interrupted by disordered phases, occur. For still larger I the lifetim e of occupied sites becom es very $s m$ all and netw ork structures are dom inated by random ness. W e develop m ethods to analyze nature and dynam ics of these netw ork pattems, give a statistical description of defects and uctuations around them, and elucidate transitions betw een di erent pattems. R esults and $m$ ethods presented can be applied to a variety of problem $s$ in di erent elds and a broad class of graphs. A im ing chie $y$ at the $m$ odeling of functional netw orks of interacting antibodies and B-cells of the im m une system (idiotypic netw orks) we focus on a class of graphs constructed by bit-chains. $T$ he biological relevance of the pattems and possible operational m odes of idiotypic netw orks are discussed.

## I. IN TRODUCTION

M any com plex coupled system s can be m odeled as networks: Vertices being associated with the system s ele$m$ ents and edges representing interactions betw een them.
 [4] ${ }_{4}^{1}$, and netw orks in the im $m$ une system (for som e approaches see [][]) are just exam ples of such system s. Frequently, although the detailed interactions of the ele$m$ ents $m$ ay be rather com plicated, the know ledge about the underlying network structure facilitates the understanding of essential features of the system as a whole [id.

In the absence of detailed know ledge about a netw orks topology previous w orks tended to assum e either a com pletely random link structure $\left[\underline{1} 1\left[\frac{1}{1}[1]\right.\right.$ or clusters given by percolation on lattices [1] []. The com plexity ofm any system $s$, how ever, em erges as a consequence of som e underlying principle for their evolution, e.g., preferential attachm ent [ [1] $\left.1^{\prime}\right]$, optim ization of transportation and com m unication pathw ays $\left[1 \overline{2}_{1}^{\prime}\left\{\overline{1}_{1}^{1}\right]\right.$ extinction of the least pop-
 has random ly evolved in time $[1]$ ]. This, altogether $m$ ay lead to a highly organized netw Ork topology.

R ecently, m uch attention has been devoted to a variety ofnetw orks w hich exhibit topological properties di erent
 taining a detailed understanding of their architecture it has proved usefiul to trace the dynam ics of the netw orks
structural grow th. A s recently observed $m$ a jor transitions in a system s dynam ics can even be com pletely govemed by preceding transform ations in its netw ork struc-

In the case of idiotypic netw orks ( $\mathbb{N} W$ 's) in the im m une system $\left[{ }^{[11} 1\right]$, dynam ics and netw ork evolution are driven by a continuous in ux of new idiotypes from the bone $m$ arrow. D ata from experim ental investigations suggest a daily bone $m$ arrow production only one order sm aller than the actual netw ork size $[$ principle goveming the dynam ics of $\mathbb{I N} W^{\prime \prime}$ 's is a set of local rules: idiotypes die out if they are under-or overstim ulated, i.e. have too few or too $m$ any neighbours. A s $C$ onw ays fam ous gram e of lifer [24] suggests, system $s$ govemed by such local rules can evolve tow ards highly

Starting from a sim ple set of rules intending to $m$ im ic the dynam ics $w$ thin idiotypic netw orks in the im $m$ une system, we present a cellular autom aton based $m$ odel for the evolution of netw orks of occupied sites on graphs. $D$ epending on the $m$ ajor param eter, the bone $m$ arrow in ux, them odelexhibits param eter regim es in which the system self-organizes into static and dynam ic pattems, show stransitions betw een such ordered phases and has a param eter range in which it is govemed by random ness. W e investigate these regim es and elucidate connections between the overall dynam ics and the evolution of the netw ork structure.

The organization of this paper is as follow s. In the next section we introduce the $m$ odel, give a brief introduction to idiotypic netw orks and outline further possible applications of our m odel. Then, in Sec. 'ITH, we give an overview over the typicalevolution of the initial dynam -
ics of the population and its connection $w$ ith changes in the netw ork structure. N ext, in Sec. 'I'IV', the stationary state and its netw ork organization w ill be characterized. In the fth section the dependence of the system squalitative behaviour on the $m$ odels $m$ ain param eter, the in ux I, w ill be explored, analytical results for sm all I derived from a microscopic view of the network characterizing uctuations around the steady state be presented and an explanation for the system s high I behaviour be given. In the nal section changes in the variety of stationary netw ork pattems form ore closely linked base graphsw ill be discussed.

The aim of this paper is not ne tuning or in detail m atching of one of the applications, but rather generally exploring features of the dynam ics caused by the w indow algorithm and understanding its connection $w$ ith netw ork structures thus evolving.

## II. THEMODELAND SOMEAPPLICATIONS

Let $G$ denote a lattice or, $m$ ore generally, an undirected connected regular graph (i.e. a graph, every of whose vertioes is linked to neighbours). Let v 2 G denote the vertices or sites and the links betw een sites ( $i ; j$ ) w th in $G$ be described by an adjacency matrix fm $\mathrm{ij}_{\mathrm{j}} \mathrm{g}_{1} \quad \mathrm{j} j \mathrm{j} j$. For sim plicity $m_{i j} 2 f 0 ; 1 g$ and $m_{i i}=0$. In the follow ing $G$ w ill also be called base graph. A vertex v 2 G can either be occupied or em pty, i.e., have occupancy $s(v)=1$ or $s(v)=0$, respectively. Em pty sites will be called holes. A vertex $v$ w ith labeli has degree $@ v=P_{j=1}^{j} \mathrm{j}_{\mathrm{ij}} \quad$. W e propose the follow ing algorithm for an evolution of occupied and em pty sites on G:
(i) Throw in I occupied vertioes, i.e. select i holes random ly and let them becom e occupied. This supply of I new occupied vertices w ill be called in ux.
(ii) Check the neighbourhood of every site v 2 G. If $v$ is occupied and has degree @v greater than $t_{u}$ or less than $t_{1}$ the vertex v will be set em pty in the next tim estep. That is: $s_{t}(v)=1!S_{t+1}(v)=0$ if $@ v<t_{1}$ or $@ v>t_{u}$. The update of (i) and (ii) $w$ ill be parallel.
(iii) Iterate (i) and (ii).
$T$ he threshold values $t_{1}$ and $t_{u}$ are $m$ odel param eters, $\mathrm{t}_{1}=0$ corresponds to no lower threshold at all. Thus, the m ain characteristics of the algorithm is a w indow of allow ed degrees. H ence we call it w indow algorithm. T he graph of all occupied vertices after iteration $t$ is nished w ill be denoted by t 2 G and $\mathrm{n}_{\mathrm{t}}=j \mathrm{t} j$ be called its population.
$N$ ote, that in the rst instance unlim ited grow th of the netw ork is prevented by the upper threshold $t_{u}$. O nce a stable structure has been established, there are no vertices violating the $m$ in im um degree rule unless vertioes
are taken out because they got too $m$ any neighbours by the last in ux. On the other hand, while $t_{u}$ leads to an instantaneous rem oval of vertices due to the $m$ ost recent in ux, the lower threshold $t_{1}$ can cause avalanches and is thus responsible for a mem ory of a perturbation which $m$ ay last over several iterations. Such avalanches are thought to adjust the netw ork structure.
$T$ hese considerationsm ake it also plain that for $t_{u}=t_{1}$ and $t_{u}=t_{1}+1$ no long lasting populations can arise. In the rst case, only a $t_{1}$ regular graph $t$ could be form ed. T hen already a sm all local reorganization w ould lead to an avalanche extinguishing the whole graph. In the second case, every vertex of $t$ is critical in a sense that it is prone to becom e rem oved by a sm all perturbation caused by the in ux.

O urm ain $m$ otivation to study such a kind ofdynam ics for the evolution of netw orks com es from trying to $m$ odel idiotypic netw orks ( $\mathbb{N} W$ s). The problem, how ever, appears to be farm ore general. Two other im aginable applicationsw illalso be sketched brie y: evolving netw orks of interacting species and, for conœeiving a vivid picture of the above algorithm, a toy system of organzing coins in a box.

## A. Idiotypic netw orks

Im $m$ une response against a broad class of antigen (bacteria, viruses, ...) is triggered by antibodies and B-œlls (which carry only one type of antibody on their surface). Schem atically this can be sketched as follow s. Perchance the antigen encounters a shape- and chargecom plem entary antibody. A ntibody and antigen thus form a com plex which $m$ arks the antigen as hostile so that it will be rem oved by another functional group of cells (e.g. killer cells). If B-cells, which carry exactly this type of antibody on their surface com e into contact w th such an antigen they becom e stim ulated, multiply into a clone and nally becom e production units' for this speci c type of antibody.

It is the basic idea of idiotypic netw orks [21] that antibodies can not only recognize antigen, but also com plem entary anti-antibodies (the speci cities of both are then also called idiotypes). This leads to stim ulation of the respective $B$-cells and thus causes a kind of a perm anent self-balanced im $m$ une activity independent ofhostile antigen.

These mutually recognizing idiotypes build the socalled idiotypic netw ork. Its vertices or nodes are represented by idiotypes, its links by functional interactions betw een them. $\mathbb{N} W$ 's are thought to play a role in, e.g., the preservation of idiotypic $m$ em ory $\left[21^{1}\right]$, the prevention of autoim $m$ unity $\left.[2], 2]_{1}\right]$, self-non-self discrim inization and cancer control.

The interaction of idiotypes within the netw ork can be
described by Lotka-V olterra like dynam ics, i.e.

$$
\frac{d x_{i}}{d t}=x_{i} @_{i}^{0}+\mathrm{f}^{0} \mathrm{X}_{j} \begin{gather*}
11  \tag{1}\\
m_{i j} x_{j} A A+
\end{gather*}
$$

where $i$ is an index labelling di erent idiotype populations, $x_{i}$ the concentration of idiotype $i$, $i$ its inverse lifetim e, f a so-called proliferation function describing the stim ulaton and death of B-cells and antibody production by stim ulated $B$-cells, and $i$ an in ux rate of new idiotype species from the bone $m$ arrow. Since secreted antibodies and those on the surface of B-cells are not explicitly distinguished a description of $\mathbb{N} W$ dynam ics as by Eq. [ $\left[\begin{array}{l}11 \\ 1\end{array}\right)$ belongs to the category ofA $m$ odels $\left[\overline{5}_{1}^{\prime}\right]$. B one $m$ arrow production is thought to be uniform ly distributed and random, i.e., there is a uniform probability for every idiotype that a $m$ em ber of its population is produced per unit of tim e.

It is a comm on approach to describe an idiotype or vertex $v$ of the $\mathbb{N} W$ by a bitstring $\left(\mathrm{v}_{1} ;::: ; \mathrm{v}_{\mathrm{d}}\right), \mathrm{v}_{\mathrm{i}} 2$ f0; 1 g of length $d$ [2d]. Reasonable estim ates for the num ber of possible idiotypes yield a bit-chain length of the order d 35 [景]. Idiotypes interact, if they are com plem entary. T his is m odelled by introducing m atching-rules' which de ne when bit-strings are connected in the above sense of com plem entarity. For instance, idiotypes can be said to interact if they are nearly exactly com plem entary or \{ in other words\{ the respective bit-strings $m$ atch allow ing for one deviating position, a m ism atch, only. G enerally, allow ing bit-strings $w$ ith m m ism atches to interact, one obtainsa $=\mathrm{P}_{\mathrm{k}=0}^{\mathrm{m}} \underset{\mathrm{k}}{\mathrm{d}}$-regulargraph $\mathrm{G}_{\mathrm{d}}^{(\mathrm{m})}$ whose links are described by an adjacency $m$ atrix $w$ th elem ents:

$$
m_{i j}^{(m)}=\begin{array}{ll}
1 & \text { if } d_{H}(i ; \bar{j}) \tag{2}
\end{array} \quad m \text { : }
$$

Reaction a nities are the stronger the better the $m$ atching of the corresponding idiotypes is. In this respect, in the sequence $G_{d}^{(1)} \quad G_{d}^{(2)} \quad$ ::: $\quad G_{d}^{(m)}$ gradually sm aller a nities are taken into account.

Som etim es it is also convenient to em ploy another view at the link structure of $\mathrm{G}_{\mathrm{d}}^{(\mathrm{m})}$. In the fram e of these bitstring $m$ odels every link is associated $w$ ith a bit-operation L , which, applied to one of the vertioes that the link connects, yields the vertex at its opposite end. For links betw een vertioes $w$ ith ideally com plem entary bit-chains $i, j$ we have $j=L_{0}$ ( $i$ ) ( $i$ is the inverse of $j$ ), for one$m$ ism atch-links $j=L_{k_{1}}$ (i) ( $i$ is obtained by inverting $j$ and changing the bit at position $k_{1}$ ), for two-m ism atchlinks $j=L_{k_{1} k_{2}}$ (i), etc. Thus, in this sense links are also labelled.

U sing a discrete version of Eq. ( $\left[_{1}^{1}\right.$ ) idiotypes are either present ( $x_{i}=1$ ) or absent ( $x_{i}=0$ ). An idiotype $v$ can survive, if it on the one hand receives at least a m inimum am ount of stim ulation from the netw ork, but is not
overstim ulated on the other hand. Too high concentrations of antibody lead to each receptor of the B-cellibeing bound to only one antibody. Since cross-linking of several antibodies is required in order to stim ulate a B-cell [151] th is leads to suppression of this idiotypes population. A m ore carefulanalysis yields that it is reasonable to assum e that the proliferation function $f$ is log-bell shaped. T hen, from the steady state conditions of Eq. $[\overline{1} \overline{1})$ one obtains a rough idea of the $m$ axim um and the $m$ inim um degree, $t_{1}$ and $t_{u}$. $N$ orm ally, onem atching antibody specity is su cient to cope with an antigen. T herefore in this m odel $\mathrm{t}_{1}=1$ which de nes the tim escales for each iteration step.

## B. Interacting species

A w idely used approach to describe the interactions of species ( $m$ acroscopic organ ism s , cells, reacting m olecules, ...) is by Lotka-Volterra like dynam ics of the type set forth in Eq. [1] ${ }^{1}$ "d]. The index inow distinguishes different species, $x_{i}$ denotes their concentrations, $i>0$ the net $e$ ect of death and birth rate, $m_{i j}$ the adjacency $m$ atrix describing their interaction structure, and $f a$ function $m$ odeling resource com petition and the e ect of predator-prey relations. N ow, a species does not require a $m$ inim um am ount of stim ulation but is still going to be restrained by the e ects of resource com petition and prey. Thus, $t_{1}=0$ and $t_{1}>0$. in this context $m$ odels a kind of $m$ utation rate, which describes the appearance of new species. Unlike in the case of the bone $m$ arrow production, is not uniform, but restricted to the neighbourhood of already existing species and also much sm aller. Though probably hard to make out, G and $m_{i j}$ describe the graph of all conceivable species and their potential interactions.

$$
\mathrm{C} \cdot \mathrm{Coins} \text { in } \mathrm{a} \text { box }
$$

Im agine a box and a heap of coins put inside initially. T hen the box will be shaken, all overlapping coins be taken out and random ly generated new heaps of coins be placed on random ly selected em pty areas of the box. This procedure will be iterated several tim es. C learly, in the above algorithm, the box corresponds to the base graph $G$, coins correspond to occupied vertioes on $G$, and em pty areas to holes. O verlapping coins have too $m$ any neighbours, thus too high a degree and will consequently be taken out. Since also isolated coins are allow ed to rem ain, the situations is that of $t_{1}=0$. $t_{u}$ represents the $m$ axim um am ount of coins which can be adjacent on a plane w thout overlap.

## III. ANALYZING THEDYNAM IC S

In this section we focus on analyzing the population dynam ics and understanding corresponding changes in the netw ork structure. Figure ${ }_{1}^{1} 1 \mathrm{l}, \mathrm{a}$ show s a sam ple tra jectory for the in itial 300 tim esteps of the population dynam ics for $\left(t_{1} ; t_{u}\right)=(1 ; 7)$ and $I=10$ on a base graph $\mathrm{G}_{12}^{(1)}$. As there seem s to be a generic evolution w ith tim e it p akes sense to look at averaged trajectories, i.e. $h n_{t} i=n_{n}(n)$ where $p_{t}(n)$ denotes the probability that after $t$ iterations $n$ occupied vertices $w i l l$ be present (see Fig. .

C learly, several phases of the dynam ics can be distinguished. First, it takes a certain time till accidentally at least a connected pair of occupied vertioes is form ed which then functions as a germ for further network grow th.

FIG.1. (a) A sam ple tra jectory for the population $n_{t}$, the giant cluster, the 2 -tree-reduced com ponent of the giant cluster ( backbone') and its 2 -leaves, see text. P aram eters are $d=12$, $\left(t_{1} ; t_{u}\right)=(1 ; 7)$ and $I=10$. (b) A veraged tra jectories of the population, the size of the greatest cluster and the average chuster size vs. tim e. A verages have been taken over 1000 independent runs, param eters are $d=8,\left(t_{1} ; t_{1}\right)=(1 ; 5)$, $\mathrm{I}=6$.

To elucidate the structure of this gem for $t_{1}>1 \mathrm{we}$ de ne three subsets of a cluster C: (i) its (generalized) $t_{1}$-leaves $l_{t_{1}}$ (C ), (ii) its (generalized) $t_{1}$-stem $s_{t_{1}}(C)$ and (iii) its (generalized) $t_{1}$-tree-reduced com ponent $r_{t_{1}}(C)$.

Leaves of the rst generation are vertices of $C w$ ith less than $t_{1}$ neighbours, i.e. $l_{l_{1}}^{(1)}(C)=f v 2 C f l a v<t_{1} g$. $T$ hen, leaves of the second generation $l_{t_{1}}^{(2)}(C)$ are vertioes of $C n l_{1}^{(1)}(C) w$ th less than $t_{1}$ neighbours. A nalogously for $\left.n=2 ; 3 ;:::, l_{t_{1}}^{(n)}=\operatorname{fv} 2 C n_{t_{1}}^{(n \quad 1)}{ }_{j}{ }_{j \mathrm{Cn} n_{t_{1}}^{(n)}}{ }_{1}\right) \mathrm{V}<\mathrm{t}_{1} g$, where $\left.@_{j \mathrm{Cn}}^{\mathrm{n}_{\mathrm{t}_{1}}^{(\mathrm{n}}}{ }_{1}\right) \mathrm{V}$ denotes the num ber of occupied neighbours of $v$ in $C n l_{S^{1}}^{(n)}$. Thus, the tree-like com ponent of $C$ is $t_{t_{1}}(C)={ }_{j=1}^{1} l_{t_{1}}^{(j)}(C)$, the stem $s_{t_{1}}=t_{t_{1}} \quad t_{t_{1}^{1}}^{(1)}$ and the tree-reduced com ponent $r_{t_{1}}=C n t_{t_{1}}$. For $t_{1}=2$ these notions coincide w ith the usual de nitions in graph theory.

C onsider the application of the w indow -algorithm with low er threshold $t_{1}$. If not sustained by random in $u x$, the $t_{1}$-stem of a chuster is prone to successively fall victim to cascades in which the $t_{1}$-leaves are taken out rst. Vertioes which are critical, i.e. are still allow ed, but will be rem oved if they lose a neighbour represent the ( $\mathrm{t}_{1}+1$ )leaves. C ontrariw ise, the ( $\mathrm{I}_{1}+1$ )-tree-reduced com ponent is the subset not endangered by avalanches caused by critical vertices.

A pparently, the tree-reduced com ponent of a cluster is invariant under step (ii) of the w indow -algorithm. So, for $t_{1}>1$ in the above context the gem which for $t_{1}=1$ is just a connected pair of occupied vertioes corresponds to a cluster w ith a nontrivialt $t_{1}$-tree-reduced com ponent. In case of, e.g., $t_{1}=2$ this is a 4-loop, for $t_{1}=3$ a cube etc. $T$ he higher $t_{1}$ the $m$ ore brganized' a germ is dem anded and the longer it takes till it is form ed perchance.

Initially, as this gem is still sm all it grow s only slow ly, since some of the new vertices are short of neighbours and thus are im m ediately taken out again. Then as a second phase of the dynam ics a phase of alm ost linear grow th of the population is entered. D uring this period alm ost all freshly throw $n$ in vertices survive, since the netw ork is already alm ost dense (thus providing enough neighbours) but still $m$ ost of the vertioes have only sm all degree. A s the num ber of vertices w ith higher degrees increases the grow th of the population then abates and reaches a m axim um. It can also be seen from F ig. ${ }^{1} \mathrm{I}_{1}^{\prime \prime} \mathrm{b}$ that during this phase alm ost all occupied vertices belong to one giant cluster. At the same time ( $t$ 150) as the $m$ axim um is reached, the giant cluster decays and sm all com ponents start to split o. Interestingly, whereas in the initial stages of the dynam ics the num ber of critical vertices is alw ays of the sam e size as the in ux, preceding the breakdow $n$ of the giant com ponent $m$ ore and $m$ ore critical vertices are assem bled (cf. Fig. '11'a). T he m axi$\mathrm{m} u m$ num ber of critical vertioes is assum ed at the sam e time (t 290) as the giant cluster breaks dow $n$.
$T$ he third phase now ensuing is $m$ arked by the complete decay of the giant cluster and a coinciding drop of the population. A s soon as this is achieved the sm aller fragm ents start becom ing rearranged, again associated w ith an increase in the population.

Finally, the system saturates into a stationary state
around which uctuations occur. The higher $t_{u}$ them ore the population is allow ed to grow in itially and the $m$ ore expressed the above described behaviour becom es. Independent of the upper threshold alw ays half of the vertioes are occupied in the nal state. Recurring to clustering properties it tums out that average as well as maxim um cluster size tend to $2: 0$. Thus, since there can't be a cluster consisting of $m$ ore than two occupied vertices this proves that for long tim es $t$ com pletely decays into 2clusters.

Holes play an im portant role in the system s approaching the steady state. A hole h w ill be called stable if it has degree @h > tu. C learly, unless it loses its property to be stable, a stable hole cannot becom e occupied. Reverting a stable hole back into a horm al hole dem ands the rem oval of @h $\quad$ of its occupied neighbours, which itself needs a rearrangem ent in the 1 -neighbourhood of these vertices. Thus, tw o characteristics of stable holes becom e obvious: (i) a hole is the m ore stable the higher its degree and (ii) whereas the change of a norm al hole into an occupied vertex dem ands only a rearrangem ent at exactly the holes place, the occupation of a stable hole requires a rearrangem ent of its whole 2-neighbourhood and needs at least tw o iterations to be com pleted.

F IG . 2. A veraged tra jectory (over 1000 independent runs) of the num ber of stable holes and of the population for $d=8$, $\left(t_{1} ; t_{u}\right)=(1 ; 5), I=2 . T$ he dotted line indicates halfthe system size $\mathcal{G}_{8}^{(1)} \dot{=} 2=128$ 。

F igure $\overline{1}$ show s an averaged tra jectory for the evolution of the num ber of stable holes and the population size. Surprisingly, even during the phase of declining population (which $m$ eans that few er occupied vertioes to $m$ ake a hole stable are available) the num ber of stable holes increases till nally in the steady state all holes tend to be stable. This can be understood from the above considerations. A s described above in detail, the reversion of a stable hole into a nom alhole requires occupied vertioes in the neighbournood of the hole to be rem oved. H ow ever, the rem oval of vertices becom es $m$ ore di cult the $m$ ore stable holes are in their neighbourhood. T hus, apparently, stable holes situated in each others (up to $2-)$ adjacency can prom ote $m$ utual stability. A s a consequence of this a form ation of alm ost 'frozen' dom ains
which are $m$ ade of $m$ utually stabilizing stable holes can be expected. These dom ains com pete $w$ th each other and nally one of them prevails and lls the com plete system. Indeed, the arrangem ent of occupied vertioes and holes in the steady state exhibits pattems which w ill be discussed $m$ ore closely in the next section.

## IV.THESTATIONARY STATE

In order to characterize the netw ork structure of the stationary state every vertex v 2 G is assigned a m ean occupancy rate $\mathrm{s}(\mathrm{v})=1=\left(\mathrm{T}_{1}, \mathrm{~T}_{0}\right) \quad \mathrm{T}_{1} \mathrm{~T}_{0} \mathrm{~S}_{\mathrm{t}}(\mathrm{v})$ and a sw itch rate $r(v)=1=\left(\begin{array}{ll}\mathrm{T}_{1} & \mathrm{~T}_{0}\end{array}\right)^{\mathrm{P}} \underset{\mathrm{T}=\mathrm{T}_{0}}{\mathrm{~T}_{1}}\binom{1}{\mathrm{sta}_{t}(\mathrm{v}) ; \mathrm{s}_{\mathrm{t}+1}(\mathrm{v})}$. $M$ ean occupancy rate and $s w$ itch rate give a $m$ easure of how $m$ any tim es a vertex is occupied or changes its occupation during the tim e interval $\left[T_{0} ; T_{1}\right]$. $T_{0} w$ illbe chosen such that the system has already reached the stationary state. This m ethod provides a way of obtaining an average picture of the occupation of .

FIG .3. M ean occupancy rate and sw itch rate for every vertex after a sim ulation on $\mathrm{G}_{8}^{(1)} \mathrm{w}$ ith param eters $\left(\mathrm{t}_{1} ; \mathrm{t}_{u}\right)=(1 ; 4)$, $I=5$. The relaxation time was chosen $\mathrm{T}_{0}=10^{4}$, then averages over $\mathrm{T}_{1}=9 \quad 10^{4}$ tim esteps have been taken. $B$ it-strings ${ }_{P} v_{7}\left(v_{1} ;::: ; v_{8}\right)$ are uniquely represented by integers $z=\begin{aligned} & 7=0 \\ & i=0 \\ & V_{i}\end{aligned}$. $^{i}$.

Figure rate of every vertex after a sim ulation on $\mathrm{G}_{8}^{(1)}$. C learly, vertices $w$ th high $m$ ean occupancy rate have a low sw itch rate and vice versa. T hus, vertices which are frequently occupied tend to be occupied alm ost perm anently; seldom occupied ones to be alm ost alw ays holes.

To elucidate the structure of the netw ork form ed by the highly active vertices we de ne the subset $S(a)=$ fv 2 G js (v) < ag containing all vertioes which are m ore frequently occupied than $w$ th rate a.

In $F$ ig. $\overline{4}$ the num ber of vertices belonging to $S(a)$ and the greatest connected cluster of $S(a)$ are shown as a function of the threshold value a. D ue to the logarithm ic scale a rst drop from $\ddagger \mathfrak{j}(\mathrm{a}) \mathrm{j}=256$ to $\mathrm{j}^{\prime}(\mathrm{a}) \mathrm{j}=130$ at $a=0$ is om itted. Two further thresholds becom e apparent: one at $a_{1} \quad 3 \quad 10^{4}$ where the size of the greatest com ponent of $S$ (a) rapidly drops to size 2 and a second one at $a_{2} \quad 0: 893$ which $m$ arks the decline in the distinction_of high - and low m ean occupancy vertices seen in Fig .

F IG . 4. N um ber of vertices belonging to $S(a)$ (see text) and the size of the greatest connected com ponent of $S$ (a) as a function of the threshold $a$. D ata taken from sim ulations on $G_{8}^{(1)} w$ ith the $w$ indow $\left(t_{1} ; t_{u}\right)=(1 ; 4)$ and in $u x I=5$. D ue to the logarithm ic scale the rst point show ing a drop of $j \in(a) j$ from j $j=256$ to 130 is left out. The dotted line indicates the level $\mathfrak{j} S(a) j=128 . D$ ata have been assem bled for $T_{1}=9 \quad 10^{4}$ iterations after a relaxation tim e $\mathrm{T}_{0}=10^{4}$.

FIG.5. Illustration of the cluster structure of the defect caused by the two vertioes $w$ ith $m$ ean occupancy rate $s s_{1}$ (draw $n$ in grey) for $=6$. These vertices are in the centre of a star-like cluster of other low m ean occupancy vertices from $\mathrm{L}_{1}$ (em pty circles). For $\mathrm{a}>\mathrm{a}_{1}$ they no longer belong to S (a) and thus their rem oval causes a decay of this cluster into ten $2-c l u s t e r s ~ o f ~ h o l e s . ~$

In order to get rid of uctuations occuring during the titerations, one can distinguish a set of high mean occupancy vertices $\mathrm{S}_{\mathrm{H}}=\mathrm{S}\left(\mathrm{S}_{1}\right)$ (which can be considered as perm anently occupied) and a set $S_{\mathrm{L}}=G n S_{\mathrm{H}}$ (corresponding to perm anent holes) of vertices $w$ th low m ean occupancy. From Fig. $\overline{1}$ one derives further that $S_{L}$ decays also into two groups, nam ely, a set $S_{\mathrm{L}_{1}}$ of 128 vertices $w$ ith $m$ ean occupancy 0 and tw o vertices (seen as a drop of $\dagger(a) j$ from 130 to 128 at $a=a_{1}$ ) $w$ th som ew hat larger $m$ ean occupancy a slightly sm aller than $a_{1}$. These 2 connected vertioes having each $1=8$ neighbours from $S_{L_{1}}$ are in the centre of a star-like cluster of low $m$ ean occupancy vertioes (cf. F ig. '은) . They represent a vertex-pair norm ally belonging to $\bar{S}_{H}$ which have accidentally been taken out and not got re led yet. $T$ hus they form a defect in the expression of a pattem structure (see section

A further clustering analysis of $S_{H}$ and $S_{L}$ reveals that both subsets of $G$ consist only of 2 -clusters. Therefore, every vertex ofv $2 S_{L}$ has exactly $@ v=1$ neighbours from $S_{H}$ and thus form $s$ a stable hole ofm axim um possible stability. This justi es the above notion of a frozen dom ain.

In case of $t_{u}=1$ a holes being stable would require at least $=t_{u}+1$ of its neighbours to be occupied. D ue to the 2 -cluster nature of the pattem, how ever, only 1 neighbours are available, so that holes cannot be stable in this case. Pattems then becom e extrem ely transient in the sense discussed below in section Ni.

## A. M etastable patterns and pattern stability

The actual steady state pattem, classi ed by groupings of vertices $w$ ith clearly distinguished $m$ ean occupancy rates, depends on the in ux I. If I is very sm all com pared to the system size $\bar{j} j$ also pattems di erent from the 2 -clustered pattem appear. $T$ he variety of such pattems is very abundant for $t_{1}=0$, becom es sm aller the $m$ ore restrictive the $w$ indow is and increases $w$ ith decreasing ratio $I=j G j$.
$T$ hey prove to be $m$ etastable, i.e. relax to a $m$ ore stable pattem and nally to the 2 -cluster pattem on very long tim escales. Interestingly, for $t_{1}=0$ both sets $S_{H}$ and $S_{L}$ prove to have exactly alike properties and thus, the system is sym metric against an exchange of occupied vertices and holes [3]d].

F igure! ${ }^{\prime}$ G gives exam ples for such a $m$ etastable pattem together $w$ ith a visualization of the ism om orphic graph structures of $S_{H}$ and $S_{L}$. Typically, they consist of a large number of $s m$ all chusters and few larger com ponents. In the organization of the netw ork structure of subclusters of $S_{H}$ and $S_{L}$ basic units (e.g. 6-loops in Fig. ('G) play a role. Nevertheless the majority of the clusters tums out to be asym $m$ etric.

In this context a com parison to random graphs on $G$ illustrates the very high organization of these pattems. A
random graph G (constructed by occupying vertices of $G$ w ith a uniform occupation probability $p$ ) will contain alm ost alw ays only one giant connected com ponent for $p>p_{c} \quad 1=[3]$ ]. Here, $m$ ultiple giant com ponents exist, although the ll ratio $\ddagger=j=0: 5$ far exceeds the percolation threshold.

Stability of a pattem is determ ined by the stability of its stable holes. T hus, a (rough) m easure for the stability of a pattem is, e.g., the average degree of its holes h@ $\mathrm{vi}_{\mathrm{v} 2 \mathrm{~S}_{\mathrm{L}}}$. It tums out that all these $m$ etastable pattems have an average hole degree slightly sm aller than that of the 2 -clustered con gurations.

F IG . 6. N ontrivialchusters $w$ hich appear in $m$ etastable pattems for $I=5,\left(t_{1} ; t_{u}\right)=(0 ; 7)$ on $G_{11}^{(1)}$. (a) 5 - and 16-clusters from a pattem built by 192 singletons, 645 - and 3216 -clusters. (b) 14-and 44-clusters from a pattem w ith w ith 208 1-, 485 -, 1614 -and 844 -clusters. (c) $2-\mathrm{T}$ ree-reduced com ponent of the 203 -chuster from a pattem consisting of 1521 -, 122 -, 123 -and 4203 -chusters ( $2-$ and 3 -chusters form chains). In the cases (a) and (b) larger clusters contain structures which resem ble the sm aller clusters. Larger loops, especially 6-loops and trees play a distinguished role. In all cases the dim ension of the cluster structures is rem arkably low.

Figure $\overline{1} \bar{T}_{1}$, show $s$ another way to quantify stability. For this purpose we apply a test in ux I. M ore speci cally, a pattem $P$ of holes and occupied vertices is taken, a number $I \quad$ むj of its holes $h$ belonging to the low $m$ ean occupancy set $S_{L}$ random ly selected and occupied, the window algorithm applied and the distance $d\left(P ; P^{0}\right)={ }_{v 2 G} \dot{S}_{P}(v) \quad S 0(v) j$ betw een the original pattem and the resultant graph $\mathrm{P}^{0} \mathrm{~m}$ easured. Intuitively, $I$ is a $m$ easure for a perturbation which is applied to the pattem. A sm allm ean deviation hd ( $\mathrm{P} ; \mathrm{P}^{0}$ ) im eans a high stability against random in ux I. For grow ing system sizes the sigm oid function hd $\left(\mathbb{P} ; \mathrm{P}^{0}\right) \mathrm{i}=\mathrm{j} j$ tends to a step function.

FIG.7. Relative $m$ ean distance hd $\left(P ; P^{0}\right) i=\leftrightarrows j$ as a function of the relative in ux $I=\Varangle j$ for pattems which arise on $G_{9}^{(1)}$. D i erent lines correspond to pattems with di erent $m$ ean cluster sizes hci which em erge for the given combinations of thresholds ( $t_{1} ; t_{u}$ ), see text. For given relative in ux pattems are the $m$ ore stable the $s m$ aller their relative $m$ ean distance.

C on $m$ ing the above ideas, $F$ ig. $\overline{1}_{1}$ visualizes tw o tendencies: (i) an upper threshold $t_{u}<\quad 1$ closer to 1
 $m$ ote the stability of pattems. Indeed, pattems w the the sam e m ean hole degree have alm ost the sam e stability characteristics hd $\left(P ; P^{0}\right) i=j$ j. For exam $p l e$, the pattems w ith $\left(t_{1} ; t_{u}\right)=(0 ; 7) ;$ hci $=8=3$ and $(1 ; 7)$;hci $=4$ whose curves coincide in Fig. ${\underset{1}{1}}_{17}^{1}$ have both a $m$ ean hole degree h@hin h $_{\text {H }}=8: 5$.

D ue to the high supply of new idiotypes from the bone $m$ arrow these pattems are $w$ thout interest for the purpose of m odelling im m une netw orks. H ow ever, it could be conceived that they prove interesting in the context of evolving species interaction netw orks where the in ux as the $m$ ean num ber of new species per tim e unit is sm all in com parison to the overall netw ork size.

> B. Stable base con gurations

The 2-clustered pattems are distinguished in two respects: (i) they are the only pattems evolving if the inux is high and (ii) they are stable, i.e., if once such a
pattem is assum ed the system will not relapse to one of the $m$ etastable pattems. T herefore we call it stable base con gurations.

The complete decay of both hole- and vertexcon gurations into 2 -clusters allows it to calculate the multiplicity of these base con gurations. It tums out that the global structure of a base con guration is already determ ined locally by xing the occupancy $s_{0}$ of one connected pair of vertices. By the know ledge of the 2 -cluster structure of $S_{H}$ and $S_{L}$ one then know sthat the vertioes in the neighbourhood of th is pair have occupancy $s_{1}=1$ S. Thus, also the occupancy of their 2 -cluster $m$ ates is xed, which in tum determ ine the occupancy of vertices in their neighbourhood and so on. By this argum ent every vertex' occupancy is uniquely determ ined since $G$ is connected. A llbase con gurations constructed in this way have been found to occur and are isom onphic to each other in the sense, that $w$ thout labelling vertioes they can't be distinguished.

A s a consequence of the above argum ent, xing $s_{0}$ and chosing one arbitrary vertex o 2 G and a link associated $w$ ith $a$ bit-operation $P$ leading to $a$ tw o-cluster $m$ ate of 0, P (o), base con gurations can be denoted by $\mathrm{B}_{\left(\mathrm{s}_{0} ; \mathrm{P}\right) \text {. }}$ H ence, the num ber of possible base con gurations is 2 . $T$ he system is degenerate, though as $2=j \mathfrak{j} j$ ! for j j ! 1 not macroscopically.

From a biological point of view it appears appealing to identify 2 -chusters $w$ ith idiotype-antidiotype pairs the antidiotype playing the role of an intemal im age
 $T$ he 2 -clusters found here, how ever, are boherent ${ }^{\prime}$ in a xed pattem of a stabe base con guration. This im plies a maximum storage capacity 2 which \{also for large system $s\{$ is far too few to account for experim ental observations.

It appears useful to consider distances betw een base con gurations. O ne nds:

$$
\mathrm{d}\left(\mathrm{~B}\left(\mathrm{~s}_{0} ; \mathrm{P}\right) ; \mathrm{B}\left(\mathrm{~s}_{1} ; Q\right)\right)=\begin{array}{ll}
8 \\
\gtrless \mathrm{G} j 2 & \text { if } \mathrm{P} Q \mathrm{Q} \text { or } \mathrm{s}_{0} \mathrm{~s}_{1} \\
\geqslant \mathrm{j} j & \text { if } \mathrm{P}=\mathrm{Q} \text { and } \mathrm{s}_{0}=1  \tag{3}\\
0 & \text { if } \mathrm{P}=\mathrm{Q} \text { and } \mathrm{s}_{0}=\mathrm{s}_{1}:
\end{array}
$$

Therefore, except the inverse con guration', base congurations di er in exactly the half of their sites from all otherbase con gurations. For the case $P \in Q$ ors $s_{0}$ half of the di ering vertioes are holes and half occupied vertioes. T hus, the di erence betw een base con guration is of the order of the system size and a change from one base con guration to another cannot take place w thout a $m$ a jor reorganization.

As the in ux I increases occupied vertioes become $m$ ore and $m$ ore prone to be rem oved. So, it can be expected that the distinction betw een highly active and scarcely active vertices loses sharpness. Increasing I over a threshold leads to a com pletely di erent behaviour of the system. P aram eter regim es in which the system ex-
hibits qualitatively di erent dynam ics will be discussed in the next section.

## V.DEPENDENCE ON THE INFLUX I

The system $s$ behaviour depends crucially on the clustering properties of $t$. To obtain a picture of the dynam ics of cluster changes the tim e-sam pled chuster size distribution over the interval $\left[\mathrm{T}_{1} ; \mathrm{T}_{0}\right], \mathrm{p}(\mathrm{c})=1=\left(\mathrm{T}_{1}\right.$ $\left.T_{0}\right)^{P}{ }_{t=T_{0}}^{T_{1}} \quad{ }_{n_{c}} n_{c} p_{t}\left(n_{c} ; c\right)$ where $p_{t}\left(n_{c} ; c\right)$ denotes the probability that $t$ contains $n_{c}$ clusters of size $c$, has been investigated. F igure $\overline{\frac{1}{1}}$, show $s$ num erical data for the cluster size distribution obtained for ve di erent values of $I$. For sm all in ux $I=20$ (Fig. ${ }^{18} \mathrm{i}$ a) the system s behaviour is dom inated by the occurence of 2 -clusters. O ccasionally also other chusters of sizes $c=6 ;::: 11$ and sizes $\mathrm{C}=16 ;:: ; 20$ appear. For $\mathrm{I}=30$ ( F ig. . ${ }^{\prime \prime}$, b ) the distribution has a structured tail of series of local extrem a. Then, for $I=40$ ( F ig. ${ }^{1} \mathrm{~B} \mathrm{C}$ ) the 2 -cluster dom inated structure is stillexpressed, but now also clusters som e orders ofm agnitude larger are found. Finally, for $I=80$ and $I=120$ ( F ig. .' idd), the chustering structure is dom inated by (depending on $t_{1}$ and $t_{u}$ ) one or severalgiant clusters and 1clusters (singletons) which $m$ ore and $m$ ore outw eigh other sm allclusters as $I$ is further increased. $I=20,40$ and 80 represent three di erent param eter regin es for the in ux which w ill be treated below .

FIG. 8. N um erical data for the cluster size distribution for di erent in uxes $I=20$ (a), 30 (b), 40 (c), 80, and 120 (d) corresponding to di erent regín es as described in the text. Sim ulations w ere perform ed on $G_{8}^{(1)}$ w ith $\left(t_{1} ; t_{u}\right)=(1 ; 5)$.

Forsm allI during the initialstages of the dynam ics the 2-cluster dom inated pattem as described in section 'IVV B' is form ed. O nce such a pattem is established I w orks as a perturbation which incidentally causes defects to the ideal pattem structure. T hese defects can be classi ed into two groups: hole'-defects and vertex'-defects (cf. F ig. . $\overline{\underline{1}} \mathbf{\underline { - 1 }} \mathbf{1})$. C learly, hole-defects are caused by 1 to correlated vertex-defects and thus are m uch less probable than vertex defects. As long as only vertex defects occur only 1 - and 2 -clusters can be form ed. H ow ever, once a hole defect is established, it serves as a junction for its surrounding $2-$ clusters and clusters of size $2+1$,
$=1 ; 2 ;::: ;$ are built. For exam ple, in Fig. $\overline{\hat{p}} \mathbf{i}$, local m axim a are found for $\mathrm{c}=7 ; 9$, and 11. T he latter one corresponds to the $m$ ost probable kind of hole defect: a form erly stable hole now is occupied and has ve rem aining occupied neighbours. In the case of the less probable chuster of size $c=9$ four once occupied neighbouns of the hole are defective, thus four are rem aining. A nalogously for $c=7$. As the 2 -clusters surrounding a hole defect $m$ ight also be defective though less frequently also clusters of even size appear. The second series of local $m$ axim a around $c=20$ in $F$ ig. Iqa can be explained by hole defects w hich are correlated, i.e., hole defects w hose occupied 2-chuster neighbours are connected.

This $m$ icroscopic picture of the process suggests a treatm ent borrow ed from equilibrium statisticalm echanics. Since defects are $m$ ore likely to occur for higher inux, I can be associated w ith a kind of a tem perature' $T(I) . T(I) w$ illbe grow ing $m$ onotonically $w$ ith I. D efects are assigned an energy' ( $t_{u}$ ) which describes the probability that a defect is caused. Since it is the harder to rem ove occupied vertiges the higher $t_{u}$ it is also expected that growswith increasing upper thresholds $t_{u}$.

In the follow ing we derive a statistical description for an ideal gas of defects.

FIG. 9. Illustration of hole-defects' (left) and ver-tex-defects' (right) for $\left(t_{1} ; t_{u}\right)=(0 ; 4)$. The defective vertex is printed in grey, holes in white and occupied vertices in black. At the left hand side one of the central holes has ve occupied neighbours and thus is stable. T he grey hole has lost tw o of its neighbours due to vertex defects'. O nly three neighbours rem ain so that the grey hole has lost its stability and can be occupied. B oth unstable and occupied holes are called hole-defects. At the right hand side the grey vertex got rem oved, causing thus a defect to the ideal 2-cluster pattem structure.

## 1. $T$ he case $t_{1}=0$

The probability to cause a vertex defect depends on the num ber of holes surrounding the occupied vertex. In spite of th is no distinction betw een defects of com pletely rem oved 2 -clusters and singletons $w i l l$ be $m$ ade. $T$ his is justi ed since for large system s an occupied vertex which rem ains after its 2 -cluster $m$ ate has been rem oved is still surrounded by alm ost the sam e num ber of holes. Furtherm ore, for $t_{1}=0$ the algorithm allow s the perm anent existence of singletons.
$T$ he probability of having 1 independent defects of energy at tem perature $1=$ (I) in an ideal pattem of $\mathrm{N}=\mathrm{j} \mathrm{j}=2$ occupied vertioes is

$$
p(1)=\frac{1}{Z} \begin{gather*}
\mathrm{N}  \tag{4}\\
\mathrm{l}
\end{gather*} \mathrm{e}^{\mathrm{l}} ;
$$

where the partition sum $Z$ is easily determ ined as

$$
Z=\mathrm{X}_{\mathrm{N}}^{\mathrm{N}} \quad \begin{gather*}
\mathrm{N}  \tag{5}\\
\mathrm{l}
\end{gather*} \mathrm{e}^{\mathrm{l}}=(1+\mathrm{e} \quad)^{\mathrm{N}}:
$$

$T$ hen the $m$ ean num ber of defects is given by

$$
\begin{equation*}
h] i=\frac{1}{\varrho} \frac{@ \ln Z}{@}=N \quad \ln i=N \frac{e}{1+e} ; \tag{6}
\end{equation*}
$$

hni being the m ean num ber of actually occupied vertices.
Comparing $w$ ith data obtained from sim ulations it tums out that the ansatz $1==I_{0}+I$ holds for a broad range of di erent values of I. From $a t$ of the $m$ ean populations w ith Eq. (') ${ }^{-1}$ ) one obtains $=88: 14 \quad 0: 48$ and $I_{0}=0: 67$ 0:18. In the whole range up to $I<35$ m ean values and probability distributions calculated by Eq. (4) are in good agreem ent w ith sim ulations (see Figs.

For very sm all I it is by sim ple com binatorics possible to obtain an approxim ation for the energies' tted from the data offig. 1 that it can cause notm ore than exactly one vertex defect, i.e. $I<2\left(t_{u}+1\right)$, the probability per site for a defect is [31]

$$
P_{d}(I)=\begin{array}{ccccccccc}
N & 1 & X^{1} & I & 1 & N & & (1) &  \tag{7}\\
I & & j=t_{u} & j & j & & I & j &
\end{array}
$$

If no $m$ ore than one defect can arise, the $m$ ean num ber of defects is given by $h l i(I)=N p_{d}(I)$ U sing Eq. ( $\overline{7}_{1}$ ) one calculates $p_{d}\left(t_{u}\right)$ and $p_{d}\left(t_{u}+1\right)$. A com parison w ith Eq. (G) yields

$$
\begin{equation*}
1 \quad\left(\ln p_{a}\left(t_{u}\right)\right)^{1} \quad\left(\ln p_{a}\left(t_{u}+1\right)\right)^{1} \text {; } \tag{8}
\end{equation*}
$$

which, e.g., evaluated for $d=8$ and $t_{u}=5$ gives $=$ $50: 8$ which is of the sam e order as the num erical value
$=88: 14$. C om paring $I_{0}$ is not reasonable, since Eq. (6), bears de cits for $s m$ all in uxes.

FIG.10. M ean population hnivs. in ux I taken from sim ulations for $\left(t_{1} ; t_{u}\right)=(0 ; 5)$ on $G_{8}^{(1)}$. The crosses represent $\operatorname{sim}$ ulation data, the line corresponds to a $t$ of hni calculated from Eq. $(\bar{G})$. F it param eters are $=88: 14$ and $I_{0}=0: 67$.

FIG . 11. P Probability distributions $p(n)=1=\left(\begin{array}{ll}T_{1} & T_{0}\end{array}\right)^{P}{ }_{t=T_{0}}^{T_{1}} \quad{ }_{n} n p_{t}(n)$ for the population size obtained from simulations on $G_{8}^{(1)}$ for $\left(t_{1} ; t_{u}\right)=(0 ; 5)$ and $I=30$ (a) and $I=20$ (b). The sim ulation results (crosses) are com pared w ith $p(N \quad n)$ from Eq. ( $\overline{\mathrm{L}} \mathrm{I}$ ) (lines connect calculated points) using $=88: 14$ and $I_{0}=0: 67$.

Indeed, the range of validity ofE q. ( ${ }^{(6)}$ ') is lim ited in tw o respects. First, although the possible num ber of defects for sm allI is lim ited by bI=tur c the sum in Eq. (ST1) extends up to N . H ow ever, for low tem peratures surplus defects are counted w ith only a sm all statisticalw eight. This approxim ation becom es w orse for high upper thresholds $t_{u}$. Secondly, too $m$ any vertex defects (which then becom e correlated) lead to hole defects. H ole defects destabilize the 2 -cluster pattem and lead to a qualitative change of the above picture.

For $t_{1}=1$ a distinction betw een tw o types of vertex defects becom es necessary. N ow, unless a new 2 -cluster $m$ ate is provided by fresh in ux during the next iteration, a singleton violates the low er threshold rule. H ence it can only survive for one tim estep.

To cope with this situation in the present fram ew ork defects consisting of a singleton (-defects) are assigned an energy , defects $m$ ade of a com pletely rem oved 2cluster pair (-defects) an energy . Both energies are expected to increase $w$ th grow ing bit-chain length $d$ and for higher upper thresholds $t_{1}$. Then a con gurations energy with $l_{1}$-and $l_{2}$-defects is $E\left(l_{1} ; l_{2}\right)=l_{1}+l_{2}$.
$T$ he probability of having $l_{1}$ independent -and $l_{2}$ defects is

$$
\mathrm{p}\left(l_{1} ; l_{2}\right)=\frac{1}{Z} \quad \begin{array}{ccc}
\mathrm{Z}=2 & \mathrm{~N}=2  \tag{9}\\
l_{1} & l_{2}
\end{array} \quad 2^{l_{1}} e^{l_{1}} \quad e^{l_{2}} \quad:
$$

For the partition sum one obtains

$$
\begin{align*}
& =(1+2 e+e \quad)^{\mathrm{N}=2}: \tag{10}
\end{align*}
$$

In analogy w ith Eq. (G) one derives the $m$ ean num ber of -defects

$$
\begin{equation*}
h h_{1} i=N \frac{e}{1+2 e+e} \tag{11}
\end{equation*}
$$

and obtains the $m$ ean num ber of -defects

$$
\begin{equation*}
h l_{2} i=\frac{N}{2} \frac{e}{1+e+2 e}: \tag{12}
\end{equation*}
$$

Finally, the num ber of em pty vertices is $n=N \quad \exists$ $2 l_{2}$, and hence the $m$ ean population is given by

$$
\begin{equation*}
\operatorname{hni}=N \frac{1+e}{1+e+2 e}: \tag{13}
\end{equation*}
$$

The ansatz $1=I_{I_{0}}+I$ is again con $m$ ed by a com parison of Eq . (13) w ith num erical data for the $m$ ean population (see Fig. (12'). T he probability distribution that $n$ vertioes are occupied at a tim $e t$ is

$$
\begin{align*}
& \text { probfn occupied vertioesg = } \\
& \ln _{\mathrm{ax}}^{\mathrm{p}} \mathrm{p}(\mathbb{N} \quad \mathrm{n} \\
& \mathrm{l}_{2}=0 \tag{14}
\end{align*}
$$

where $l_{n} a x=b N=2 \quad n=2 c$ and $p\left(\nexists ; l_{2}\right)$ as given by Eq. $\left(\underline{1} \bar{q}_{1}\right)$.

FIG. 12. Them ean population for $G_{10}^{(1)} \mathrm{w}$ ith $\left(\mathrm{t}_{1} ; \mathrm{t}_{\mathrm{u}}\right)=(1 ; 5)$. Fitting w ith Eq. (133) leads to $=632$ 99, $=250: 6$ 13:1, and $I_{0}=36: 1 \quad 4 \cdot 2$. The tbreaks dow $n$ if one tries to include the range I 150 which $m$ arks the onset of the transition

A nalytical results derived from Eq. (14) are again in good agreem ent w ith sim ulation data (see Fig. (13).
 tions as in the case for $t_{1}=0$.

FIG. 13. C om parison between simulation data for the probability distributions of the population size for $\mathrm{G}_{10}^{(1)}$, $\left(t_{1} ; t_{u}\right)=(1 ; 5)$ (a) $I=25$ and (b) $I=80$ and results derived from Eq. (14) for the same, , and $I_{0}$ as in $F$ ig. 1121 . In (b) the in ux is already high enough that both types of defects appear with alm ost equal probabilities.

## B. The transition region

A s previously discussed increasing I beyond a threshold leads to a grow ing number of hole defects. The appearance of correlated hole defects is connected w ith
the form ation of great clusters consisting of connected 2clusters. A s I becom es still larger, the probability that hole defects becom e correlated increases. O ccasionally this leads to the em ergence of a giant chister (see F ig. ${ }^{\prime}=$ the di erent series of localm axim a correspond to an increasing num ber of connected hole defects). Speaking in the language of them odynam ics, grow ing in ux entails a grow th of uctuations which nally tend to overthrow the regular pattem structure.

F IG. 14. Sim ulation data for $G_{8}^{(1)},\left(t_{1} ; t_{u}\right)=(1 ; 4)$. (a) show S the population $n$, the num ber $h$ of stable holes, and the size of the greatest connected com ponent of $t$, gc. In itially, approxim ately half of all sites on $G_{8}^{(1)}$ becom e stable holes and a pattem is assum ed. (b) shows a transition region. T he num ber of stable holes $h$ and the population $n$ drop suddenly, a giant chuster is form ed. (c) show $s$ the sm allest and the second sm allest distance to a stable base con guration $m_{1}$ and $m_{2}$ (cf. text). In the transition region no pattem is selected. (d) displays a num ber for the pattem which has the sm allest distance to $t$. In the transition region betw een two shanply assum ed pattems the state changes quickly. Fort2 [200;1700], $k_{m \text { in }}=5$, for $t>2000, k_{m \text { in }}=4$.

FIG.15. C om parison betw een the $m$ ean occupancy distributions $m$ easured in a transition region (left) and during the tim e to the transition region (right). In the right hand gure a 2 -clustered pattem is assum ed.
$T$ he building of a giant cluster requires the reversion of a m a jor fraction of the stable holes into norm al holes. Thus, since stable holes form the skeleton fram ing' of the pattem structure, the system relapses into a phase where no pattem lasts for a longer tim espan.

Figure ${ }^{1} \overline{1}_{1}^{\prime}$ illustrates this behaviour for a sim ulation on $\mathrm{G}_{8}^{(1)} \mathrm{w}$ ith $\left(\mathrm{t}_{1} ; \mathrm{t}_{u}\right)=(1 ; 4)$. In itially, after the rst stages of the dynam ics the system settles into a steady state. For better illustration every stable base con guration $B\left(s_{0} ; P\right)$ is given a unique num ber $\mathrm{k} ; \mathrm{k}=1 ;:: ; 18$. In F ig. ${ }^{1} 14_{1}^{-} \mathrm{C}$ the $m$ inim um distance

$$
\begin{equation*}
m_{1}=m_{k} \text { in } d\left(t ; B_{k}\right) \tag{15}
\end{equation*}
$$

and the second sm allest distance

$$
\begin{equation*}
m_{2}=\min _{k \notin k_{m} \text { in }} d\left(t ; B_{k}\right) \tag{16}
\end{equation*}
$$

to any stable base con guration are shown. For the time intervals [200;1700] and [2000;3000] it holds $\mathrm{m}_{1} \mathrm{~m}_{2}$. C onsequently the system is in the stable base con guration $B_{k_{m} \text { in }}$. Incidentally, hole defects associated $w$ ith the em ergence of larger clusters appear. M ostly, as long as hole defects rem ain uncorrelated, they are repaired during the next iterations. At $t 1700$ the exact lock in of state $\mathrm{k}_{\mathrm{m}}$ in $=5$ is lost and for $\mathrm{t} 2 \mathrm{I}_{\text {change }}=[1700 ; 2000]$ a phase $m$ arked by frequent changes of $k_{m}$ in is entered. D uring this period $m_{1} \quad m_{2}$ and thus no base con guration is sharply assum ed. A com parison of vertex $m$ ean occupancy rates during this phase and the previous one justi es to speak of the tim e-intervalt $2 I_{\text {change }}$ as of a disordered period, since, clearly, any distinction betw een high $m$ ean occupancy and low m ean occupancy vertioes is lost. A s expected, the em ergence of the disordered phase goes hand in hand w ith the form ation of a giant connected com ponent in $t$, a drastic loss of stable holes, and a drop in the population.

The whole dynam ics of the system is $m$ arked by a sequence of ordered and disordered phases. As I is increased, the residence tim e in ordered phases declines till nally the frequency of base con guration' changes (dened as a change of $\mathrm{k}_{\mathrm{m}}$ in ) tends to one. T hus, the system becom es com pletely disordered.
$F$ igure ${ }^{1} 1 \underline{1}$ displays simulation data on $G_{10}^{(1)}$ with $\left(t_{1} ; t_{u}\right)=(1 ; 8)$ for the $m$ ean tim $e$ (residence tim e) during which $k_{m}$ in rem ains unchanged. A $n$ abrupt transition from a phase $m$ arked by perm anent pattems to a phase of transient pattems interrupted by periods of disorder occurs at $I_{c} \quad 270$. A ccordingly, as can be seen from $F$ ig. [1] $7_{1}$, the $m$ ean lifetim e (averaged over all vertices) drops abruptly during this range of in uxes. For I > 300 m ean lifetim es decay exponentially and quickly tend to one. Very short lifetim es, how ever, do not allow for static order orm em ory. A pparently, the transition from order to disorder goes through a phase ofm ore and $m$ ore frequent pattem changes.

F IG . 16. M ean residence tim e, i.e. tim e during which $k_{m}$ in rem ains unchanged (excluding a relaxation tim ef the rst 5000 tim esteps). A 11 sim ulations on $G_{10}^{(1)} \mathrm{w}$ ith $\left(t_{1} ; t_{u}\right)=(1 ; 8)$ have been allow ed to run for $10^{5}$ tim esteps. For $I<I_{C}=270$ no change of $k_{m}$ in has been found.

FIG.17. M ean lifetim e vs. in ux I obtained from sim ulations on $G_{10}^{(1)}$ for $\left(t_{1} ; t_{u}\right)=(1 ; 8)$. T he $m$ ean lifetim $e w a s$ determ ined after allow ing 5000 tim esteps for relaxation to a steady state. For every I the sim ulations then run for 95000 $m$ ore iterations. D ata for $I<100$ are not show $n$ since $m$ ean lifetim es exceeded sim ulation tim es.

## C. H igh I > $I_{c}$ : Iterated $m$ aps

For in uxes $I>I_{c}$ the lifetim e ofoccupied vertices becom es very short. $T$ his indicates that the system can no longer form ordered pattems and long-tim e correlations between the system s con gurations disappear. Thus, while for low in ux clearly $\mathrm{hn}_{\mathrm{t}+1} \mathrm{i}$ is an intricate function of both the system $s$ con guration $t$ at tim estep $t$ and the $m$ ost recent in $u x$, for high in uxes the $m$ ean population at tim estep $t+1$ tends to depend only on the size of $I$ and the $m$ ean population at the previous tim estep. A lso, from the $m$ ean occupancy distributions one con jectures, that the structure of $t$ is essentially random, i.e. obtained by random ly occupying $j$ t jvertices of the base graph G .

If one random ly occupies $n$ sites of a base graph $G$ the relative $m$ ean num ber $h(n)$ of occupied sites after sites $w$ ith degrees outside of $\left(t_{1} ; t_{u}\right)$ have been rem oved is
given by

C onsidering a large random in ux, apart from uctuations the relative population $x_{t} w$ ill evolve according to $x_{t+1}=h\left(I=j G j+x_{t}\right)$. Thus, in the steady state $\mathrm{x} w i l l$ preferably assum e values near the stable xed points of the shifted function $g(x)=h(I=j G j+x)$, i.e. near the solutions of $x^{?}=g\left(x^{?}\right)$. Linear stability analysis yields that a xed point is stable if $j 0\left(x^{?}\right) j<1$. A nalogously, $n-$ cycles $f x^{?} ; g\left(x^{?}\right) ; g^{(2)}\left(x^{?}\right)=g\left(g\left(x^{?}\right)\right) ;::: ; g^{(n \quad 1)}\left(x^{?}\right) g$ are solutions of $g^{(n)}(x)=x$ and are stable if $\mathrm{g}^{(n)} 0\left(x^{?}\right) j<1$.

For $=11$ and $\left(t_{1} ; t_{u}\right)=(1 ; 8) g(x)$ is a function $w$ ith one $m$ axim um. C onsequently, one expects that $g^{(n)}$ has at $m$ ost $n \mathrm{~m}$ axim a. Thus, in principle, cycles of higher order are possible.

FIG.18. Thebifuraction diagram obtained by iterating the function $g(x)$ in com parison to sim ulation results for the $m a x-$ im a of the population histogram for $\left(t_{1} ; t_{u}\right)=(1 ; 8)$ on $G_{10}^{(1)}$ ( lled squares connected by lines). Solid lines correspond to stable branches, dashed lines to unstable branches. T he region of the sim ulation data where three stable solutions coexist corresponds to the onset of disorder: T he interm ediate branch represents the $m$ ean population during periods in which the system closely assum es a base con guration, the upper and the lower branch are data sam pled during disordered phases. Especially for higher in ux sim ulation results and the data obtained by iterating $g$ are in very good agree$m$ ent. T he sm aller diagram $s$ visualize changes in the stability of xed points of $g$ at the branching points: (a) $g$ (solid line) becom es unstable at $I=j G=0: 2$, but $g^{(2)}$ (dashed line) is stable. H ence a cycle appears. (b) At $I=j \mathcal{j}=0: 3$ also $g^{(2)}$ (solid line) becom es unstable and $\left\{\right.$ since $g^{(3)}$ (dashed line) gives only one unstable solution \{ a 4-cycle em erges. (c) At $I=j G j=0: 45 \mathrm{~g}^{(2)}$ becom es stable again leading to a backw ard bifurcation and a 2 -cycle.

The function $g(x)$ is a polynom ial of order $t_{u}$. Thus
$g^{(n)}$ is of order $\hbar_{u}^{n}$ and there is no general analytic solution to $x^{?}=g^{(n)}\left(x^{?}\right)$. As an exam ple we consider the case $\left(t_{1} ; t_{u}\right)=(1 ; 8)$ on $G_{10}^{(1)}$, i.e. $=11$ and $j \underset{G}{ } j=1024$. Evaluating the xed point equations num erically, one obtains the bifurcation diagram displayed in F ig. 1 $x=0.2$ one nds a forw ard pitchfork bifurcation tow ards a 2 -cycle, which then at $x=0: 3$ becom es also unstable, leading to the em ergence of a 4 -cycle. For $x=0: 45$ this 4 -cycle is found to becom e unstable and a backw ard pitchfork bifurcations leads again to a stable 2-cycle. Far outside the region of biological interest, for $\mathrm{x}=0: 93 \mathrm{a}$ backw ard bifurcation occurs and the single xed point solution again becom es stable. Figure 11d also displays data obtained from sim ulations of the window algorithm on $G_{10}^{(1)}$ which exhibit the sam e qualitative behaviour as the iteration of $g$. A s expected, deviations becom e sm all as I increases.

## VI.M ORE DENSELY $W$ IRED SYSTEM S: TW O-M ISMATCH BASE GRAPHS

In this Section som e observations about the dynam ics created by the $w$ indow algorithm $w$ th $t_{1}=1$ on $m$ ore densely w ired base graphs w illbe presented. A s a consequence of a higher coordination num ber di erent static pattems and a new type of dynam ic pattem can be observed. In principle, we expect (i) m ore sparsely populated, and hence transient pattems of reduced stability for low $t_{u}$ and (ii) enhanced stability for upper thresholds close to 1 (cf. Sec.i'IV À Í).

As an extension of the base graphs $\mathrm{G}_{\mathrm{d}}^{(1)}$ whose link structure is created by bne-m ism atch links' we now introduce additional links connecting bit-chains which deviate in two positions from com plem entarity, so de ning the base graphs $\mathrm{G}_{\mathrm{d}}^{(2)}$, cf. Eq. ( $\bar{Z}_{2}$ ).
$C$ learly, since $G_{d}^{(1)}$ is connected such tw o-m ism atch links of $\mathrm{G}_{\mathrm{d}}^{(2)}$ are shortcuts of paths in $\mathrm{G}_{\mathrm{d}}^{(1)}$. For exam ple, referring to the notion of bit-operations associated with
 $k_{1} \not k_{2}$, are also linked by the six paths corresponding to combinations of the edges $\mathrm{L}_{0}, \mathrm{~L}_{\mathrm{k}_{1}}, \mathrm{~L}_{\mathrm{k}_{2}} 2 \mathrm{G}_{\mathrm{d}}{ }^{(1)}$.

A though every vertex now acquires $d(d \quad 1)=2$ new edges the form er link structure is conserved. Thus, it could be conceived that pattems created on $G_{d}^{(2)} r e-$ tain a part of the structure of the stable base con gurations which are form ed on $\mathrm{G}_{\mathrm{d}}^{(1)}$. C ounting, e.g., two$m$ ism atch' links in a base con guration $B{ }_{\left(s_{0} ; F_{1}\right)} \quad G_{d}^{(1)}$ one nds that every occupied vertex now acquires $d$ new links on $\mathrm{G}_{\mathrm{d}}^{(2)}$ (cf. Fig. 11 d ), aggregating to a total degree $d+1$. Thus, this kind of pattems is forbidden for $t_{u}<d+1$. However, it tums out that apart from $m$ etastable structures for $s m$ all in ux the dynam ics alw ays ends up in the above described con gurations. $T$ hus, for $t_{u} d+1$ the base-graph $G_{d}^{(2)}$ alw ays decays
into tw o groups ofhigh $m$ ean occupancy vertioes $S_{H}$ and low $m$ ean occupancy vertices $S_{L}$. B oth, $S_{H}$ and $S_{L}$ form $(d+1)$-regular subchusters of ${ }_{d}^{(2)}$. Resum ing the considerations ofSec. 'iV Bi one nds that these stable base congurations on $\mathrm{G}_{\mathrm{d}}^{(2)}$ have m ultiplicity 2d. The scenario for grow ing in $u x$ is the same as on $G_{d}^{(1)}$ : for $I>I_{c}$ phases of well-de ned base con guration are interrupted by disordered periods leading to pattem-changes, and nally to a dynam ics $m$ arked by random ness and very short lifetim es.

FIG. 19. An illustration of how two-m ism atch links' (dashed line) contribute to the degree of occupied vertices in a base con guration $\mathrm{B}_{\left(\mathrm{s}_{0} ; \mathrm{L}_{1}\right)}$. O ccupied vertices in $\mathrm{B}_{\left(\mathrm{s}_{0} ; \mathrm{L}_{1}\right)}$ are draw $n$ in black, em pty ones in white. Two-clusters (e.g. o and $p$ ) in B are connected via the one-m ism atch link' (solid line) $L_{1}$. Except o the one $m$ ism atch neighbours $h_{j}=L_{j}(p)$, $j \neq 1$, of $p$ are holes. A part from the holes' 2 -cluster $m$ ates $\mathrm{L}_{1}\left(\mathrm{~h}_{\mathrm{j}}\right)$ all their neighbours are occupied. If one pursues an inversion link $L_{0}$ from any such hole $h_{j}$ adjacent to $p$, a vertex $q=F_{0}\left(h_{j}\right)$ is reached which is \{via $L_{1 j}\{$ also a twom ism atch neighbour of o. O ne can easily verify that o has no other occupied two mism atch neighbours'. Consequently, in a base con guration $B$ on $G_{d}^{(2)}$ every occupied vertex has $d+1$ occupied neighbours.

H ow ever, for $t_{u}<d+1$ where relics' of pattems form ing on $G_{d}^{(1)}$ are no longer allow ed the behaviour tums out to be $m$ ore interesting.

FIG.20. M ean lifetim e (log-scale) vs. in ux for sim ulations on $G_{12}^{(2)}$ with $\left(t_{1} ; t_{u}\right)=(1 ; 10)$. Successively, the system form $s$ cube-pattems, $m$ ultiple-group pattems, singleton pattems, and again multiple-group pattems. T hen, pattems becom e transient and nally a random ness-driven regim e is entered (see text).

As tools to investigate the structure of netw orks we
again consider the $m$ ean occupancy rates of all vertiges and probe the $m$ ean occupancy-pattems by de ning subsets $S$ (a) $\quad G_{d_{-}}^{(2)} w$ th di erent threshold-occupancy rates a (see Sec. 'IVI). In analogy with results for the one$m$ ism atch case we nd m etastable pattems for sm all inuxes. D epending on the ratio $I=G_{d}^{(2)} j$ rst com pletely 2-clustered, 4-clustered or 8-clustered pattems appear (4clusters are chains, 8 -clusters cubes). N ext in a range of in uxes cube-con gurations dom inate (cf. Fig. $\mathrm{Z}_{2} \mathrm{O}_{1}$ ). D ifferent from the 2 - and 4 -cluster pattems, how ever, the cubes don't 11 the base-graph com pletely and 256 vertioes not $m$ atching in the cube pattem are left.

FIG.21. E very vertex'm ean occupancy obtained by a sim ulations on $G_{12}^{(2)}$ w th $\left(t_{1} ; t_{u}\right)=(1 ; 10)$ and $I=30$. Vertices are labelled by integers $z$ corresponding to their respective bit-chains. The relaxation time was $\mathrm{T}_{0}=5000, \mathrm{~m}$ ean occupancies have been sam pled over $T_{1} \quad T_{0}=15000$ further tim esteps. A n o set has been added to display the group $S_{L}$ w th the low est m ean occupancy hai $\mathrm{S}_{\mathrm{L}}=0$. T he interm ediate group $S_{M}$ hasm ean occupancy hai $i_{M} \quad 0: 01$, the group w ith highest $m$ ean occupancy hais h $_{H}$ 1:0.

F igure'21' show s data for every vertex' m ean occupancy obtained by a sim ulation on $G_{12}^{(2)}$ w ith $\left(t_{1} ; t_{u}\right)=(1 ; 10)$. $T$ he set of vertiges $w$ th highest $m$ ean occupancy $S_{H}$ decays into cubes, the set $w$ th lowest m ean occupancy $S_{L}$ form $s$ a giant com ponent of 2816 vertices. $S_{L}$ consists of 1536 alm ost never occupied vertices of degree $@_{j G n S_{L}}=61,256 \mathrm{w}$ ith $@_{j G n S_{L}}=43$ and 1024 w ith $@_{j G n S_{L}}=39$. A $l l$ degrees are larger than $t_{u}$ and thus $S_{L}$ entirely consists of stable holes. $T$ he 256 vertices not exactly $m$ atching in the cube pattem form a subset $S_{M}$ of interm ediate $m$ ean occupancy. $S_{M}$ tums out to contain only singletons, each of which is surrounded by elem ents of $S_{L}$ which are alm ost never occupied. Thus, vertiges of $S_{M}$ are isolated spots of activity sustained by in ux tem porarily placed at their surrounding stable holes, but taken out im m ediately afterw ards due to overstim ulation. C onsequently, as long as no fresh in ux is placed adjacent to $i t$ in the next tim estep a vertex of $S_{M}$ dies out one tim estep after it has been inserted. This view is con m ed by very short $m$ ean lifetim es $\mathrm{hT}_{\text {life }} i_{\mathrm{S}_{\mathrm{M}}} \quad 1$ of elem ents of $S_{M}$, which slightly grow w ith increasing inux. Together w ith a grow ing probability that isolated
holes get lled this accounts for relatively large m ean occupancies hai $i_{M}$ in comparison to hai S $_{S_{L}}$. Though at the rst glance surprising that a vertex can survive at a site where it is surrounded by alm ost alw ays em pty sites, this but indicates a mechanism which is to prevail in a consecutive regim e: isolated vertices of high durability are sustained by quickly uctuating short-living in ux in their neighbournoods.

F IG . 22. M ean occupancy rates of vertices $z$ derived from a sim ulation on $G_{12}^{(2)}$ w ith $\left(t_{1} ; t_{u}\right)=(1 ; 10)$ and $I=100$. Six groups of vertices $S_{1}$;:::; $S_{6} \quad G_{12}^{(2)}$ can be distinguished by their $m$ ean occupancy.

Increasing I over approxim ately 80 the cube pattems becom e unstable and from I 100 onw ards a pattem $m$ arked by 6-levels of $m$ ean occupancy (see $F$ ig. ${ }^{2} 2 \overline{2}$ ) is chosen. In contrast to the appearance of several levels of $m$ ean occupancy due to transitions betw een isom orphic stable base con gurations this grouping is of a di erent nature. W hile in the rst case sim ulations started with di erent initial conditions lead to di erent num bers of groups and changing $m$ ean occupancy levels (depending on the tim estep when transitions occur) sim ulations perform ed w th di erent in itialconditions now alw ays reproduce these 6 groups and their $m$ ean occupancies.

| group $S$ | $j$ j $j$ | hC $i$ | hi | hri | hf $_{\text {sm alli }}$ | hC $i_{\text {sm all }}$ | hni |

TABLE I. D ata characterizing the 6 groups $S_{1},:::, S_{6}$ obtained from simulations on $G_{12}^{(2)}$ with $\left(t_{1} ; t_{u}\right)=(1 ; 10)$ and $I=100$. In 30000 tim esteps vertices of $S_{1}$ have alw ays belonged to the greatest subcluster of $t$, hence hC $i_{\text {sm all }}$ could not be $m$ easured. Since they are im m ediately taken out after they got into the system stable holes have a m ean lifetim e $\mathrm{h} i=0: 0$. This $m$ eans that there $m$ ean lifetim $e$ is shorter than the discretization of tim $e$.

The intervalofin uxes I $2[80 ; 100]$ is characterized by transitions betw een both types of pattems in the course of which for higher in uxes periods during wich the 6group pattem is assum ed $m$ ore and $m$ ore prevail. The change of the $m$ ean population averaged in both types of pattem is drastic: for $I=90$ the cube-pattem can sustain approxim ately hni 1024 vertices while at the onset of their appearance 6-groups pattems can support a mean population of only about hni 600 occupied sites. C om paring the $m$ ean occupancy levels of the 6group pattem w ith all previous pattem structures one rem arks that, while groups of always em pty sites are stillpresent, groups of alm ost perm anently occupied vertioes are lacking. A ll groups have $m$ ean occupancy rates $s m$ aller than $0: 7$. This, and the relatively short lifetim es of vertices belonging to the groups $S_{4} ; S_{5}$, and $S_{6}$ w ith high $m$ ean occupancy, speaks in favour of an intenpretation as a dynam ic' pattem. O ccupied vertices belonging to di erent groups 'uctuate' w th di erent rates, while the interplay of them secures that the distinct role of the groups is preserved. In the follow ing the nature of this dynam ic pattem willbe elucidated in $m$ ore detail.

F igure 22 and Table '1. groups: $m$ ean size of the cluster hC i on $t$ that a vertex of a group belongs to, its $m$ ean lifetim $e h i, m$ ean sw itch rate hri, the $m$ ean frequency $\mathrm{hf}_{\text {sm all }}$ i ofbelonging not to the giant com ponent and the $m$ ean cluster size $h C i_{\text {sm }}$ all of the sm all clusters if the vertex is not in the greatest com ponent of $t$. On average elem ents of $S_{1} ; S_{2}$, and $S_{3}$ belong to 371 -clusters on $t$, but are very seldom m em bers of sm all clusters or singletons, have relatively short lifetim es and high sw itch rates. In contrast, ele$m$ ents of the groups of higher $m$ ean occupancy $S_{4} ; S_{5}$, and $S_{6}$ typically have $s m$ aller $m$ ean cluster-sizes, form m ore frequently sm all clusters, preferably singletons, and have long lifetim es. M ean lifetim es are increasing with increasing $m$ ean occupancy of the groups.

Exploring the interconnectedness and netw ork structure of the groups $S_{1} ;::: ; S_{6}$ one obtains the follow ing picture (cf. Fig. 2tid): The strongly interconnected groups $S_{2}$ and $S_{3}$ form a core of $G$ to which \{except $S_{4}\{$ all the other groups are attached. Excluding this core, each of the other groups consists of singletons. T he largest set $S_{1}$ is a reservoire of stable holes and connects $S_{4}$ w th the core. Thus, vertioes of $S_{4}$ play a sim ilar role as the previously $m$ entioned isolated holes in the cube-pattem: they receive their whole sustenance from the in ux and have no perm anent connections. W hile the group of second largestm ean occupancy, $\mathrm{S}_{5}$, has only links to the less populated part of the core, $\mathrm{S}_{2}$; the m ost active vertices, elem ents of $S_{6}$, have connections w ith both parts of the core.

C onsequently, apart from stim ulation by random inux elem ents of $S_{5}$ obtain stim ulus from the core-group $S_{3}$. N evertheless, the stim ulation is not optim al leading to a $m$ ean occupation of only $1=3$ of $S_{5}$. The group $S_{6}$ receives stim ulation from both core groups and so can
support a higher population than $S_{5}$. C ontrarily, since being strongly interconnected and connected to both the richely populated groups $S_{5}$ and $S_{6} \mathrm{~m}$ ost vertices of $\mathrm{S}_{2}$ are suppressed. In the case of $S_{3} w$ hich does not connect to $S_{5}$ suppression is lower and thus a higher $m$ ean population can be sustained. The data shown in Table ${ }_{1}^{2}$ are in qualitative agreem ent $w$ ith this interpretation.

F igure $1_{2}^{2} \overline{2}_{1}^{\prime}$ displays sim ulation data for the change of the relative occupations $s_{i}=1=j_{i} j$ v2 $s_{i} s(v), i=1 ;:: ; 6$, of the 6 groupsw ith increasing in ux. Initially, allgroups are clearly distinct, groups 4-6 have relatively low occupation and the $m$ ean populations of $S_{2}$ and $S_{3}$ are clearly above zero. A s I grow s while $S_{2}$ and $S_{3}$ lose population $S_{4}, S_{5}$ and $S_{6}$ becom e $m$ ore populated, but at di erent rates. Thus, at I 150 the groups $S_{4}, S_{5}$ and $S_{6}$ becom e united leading to the form ation of a single set $S_{H}$ of high m ean occupancy vertices. Sim ilarly, in the case of $S_{1} ; S_{2}$, and $S_{3}$. For I 140 group $S_{2}$ joins $S_{1}$ and becom es indistinctive from $S_{3}$ at I 175 leading thus to a single low occupancy group $S_{\text {L }}$. D uring this process the overall $m$ ean population of $t$, hni, is grow ing. C onsequently, for I 2 [175;220] again a 2-group pattem of 1124 high $m$ ean occupancy and 2972 low $m$ ean occupancy vertices appears, consisting now entirely of long living singletons sustained by the in $u x^{\prime}$. Transition pattems before this pattem appears are 5-and 4-group pattems, after it grew unstable 3-group pattems are form ing.

As I is further increased the in ux which heretofore guaranteed the sustenance of $S_{5}$ and $S_{6}$ gradually causes overstim ulation. Thus, the $m$ ean populations of $S_{5}$ and $S_{6}$ are shrinking, causing in tum less overstim ulation to the core. So, again a sm all population can persist in $S_{2}$ and $S_{3}$. A ltogether, for further increased in ux the di erent groups disentangle, leading to a revival of the multi-group pattems.

FIG.23. V isualization of the netw ork structure of the groups $S_{1}, \ldots, S_{6}$. The squares indicate $m$ any connections of vertices of a group am ong them selves, isolated circles in a group visualize that it consists of singletons. T he thickness of the connecting lines gives a m easure of the num ber of links connecting elem ents of di erent groups. Because of their im portance for the existence of giant com ponents in $t$ the core groups $S_{2}$ and $S_{3}$ are bounded by fat lines. Larger boxes correspond to larger groups.

From I 260 on these dynam ic multiple group pattems becom e unstable and rearrangem ents betw een different (isom onphic) con gurations set in. A nalogous to the scenario discussed in Sec. "N'Bl' disordered periods $m$ ore and $m$ ore dom inate and nally lead to disorder.

Interestingly, the group structure allow s som e insight into the actual cluster structure of $t$ at an arbitrary tim estep. Obviously, giant and greater chusters on $t$ can only em erge as long as the core is populated. As the $m$ ean population of $S_{2}$ does not su ce to form $a$ giant com ponent w thin $S_{2}, S_{3}$ functions as the glue' of giant clusters on $t$. E lem ents of the backbone' of the giant cluster preferably come from $S_{2}$ and $S_{3}$. As the population of $S_{2}$ decreases vertioes of $S_{5}$ increasingly becom e detached from the core and tend to form sm all clusters and singletons.

A great com ponent, how ever, is still retained by ele$m$ ents of $S_{6}$ and $S_{2}$ bound together by $S_{3}$. A s the population of $S_{2}$ also sinks below a certain threshold, greater com ponents of $t$ becom e star-like, their hubs being in $S_{3}$. Finally clusters di erent from singletons com pletely vanish, resulting in purely in ux sustained pattems of singletons.

## VII.PATTERNSFOR $\mathrm{t}_{1}>1$

For com pleteness in this section stationary pattems appearing for lower thresholds $t_{1}>1 \mathrm{w}$ ill be sketched brie $y$.

F igure ${ }^{2} \overline{2}^{2} \mathbf{F}_{1}^{\prime}$ displays data for the m ean occupancy rates of every vertex gathered from a sim ulation on $G_{11}^{(1)}$ with $\left(t_{1} ; t_{u}\right)=(3 ; 10)$. O ne realizes tw o relatively broad bands of $m$ ean occupancy rates. Investigating the structures of $S_{H}=S(0: 5)$ and $S_{L}=G n S_{H}$ reveals that, analogously to the $t_{1} \quad 1$-situation both high- and low m ean occupancy groups com pletely decay into $2-\mathrm{clu} s t e r s . \mathrm{N}$ ow , how ever, such 2 -cluster pattems are only existing $w$ ith $m$ ean occupancy rates hai ${S_{H}}$ signi cantly sm aller than 1 and hais far above zero. Thus, since a frozen' 2clustered state (see Sec. ${ }_{[\underline{I I T}}^{-\overline{I I})}$ can not subsist for $t_{1}>1$, a uctuating 2 -cluster pattem is form ed. At every single tim estep only a part of the high -m ean occupancy vertices is occupied. A s a consequence, not all holes are stable. A part of the holes can becom e occupied, thus giving the necessary stim ulation to the vertioes of $S_{H}$ which are present. On average, whereas elem ents of $S_{L}$ have high degrees (and are on the verge of being overstim ulated) elem ents of $S_{H}$ have low degrees (and are threatened by understim ulation). O n the whole, how ever, vertioes occupying holes tend to get rem oved w ith higher probability. O ne can im agine this situation as a pattem of long living occupied 2 -clusters own round by short living 1-and 2-clusters, living just for their stim ulation.

FIG . 24. R elative occupation $s_{i}=1=j S_{i} j^{P}$ v2 $s_{i} S(v)$ of the 6 groups (labelled by their group num ber) for di erent inuxes. For I 140 groups $S_{1}$ and $S_{2}$ unite, for I 175 $S_{3}$ joins them. At I $220 S_{3}$ again becom es separated, for I 240 also $S_{2}$ disjoins from $S_{1}$. Sim ilarly, $S_{4}, S_{5}$ and $\mathrm{S}_{6} \mathrm{~m}$ erge at I 150. This leads to 5-group pattems (I 2 [140;150]), 4-group pattems (I 2 [150;175] and I 2 [240;260]), singleton-pattems (I 2 [175;220]) and a 3-group pattem (I 2 [220;240]). For I > 260 transitions betw een isom orphic con gurations set in.

FIG.25. The m ean occupancy rate of every vertex from sim ulations on $G_{11}^{(1)}$ w ith $\left(t_{1} ; t_{u}\right)=(3 ; 10)$ and in uxes $I=150$, 300 and 500. For low in ux both high-m ean-occupancy group and low m ean-occupancy group are considerably apart from their extrem e values 1 and 0. As I grow $S$, $S_{L}$ becom es less occupied and vertices of $S_{H}$ evolve to alm ost perm anent presence. Thus, increasing I further the high m ean occupancy set loses stim ulation and the pattem becom es unstable.

C onsidering this situation as evolved from an ideal2cluster pattem $B_{\left(s_{0} ; P\right)}$ ) one understands that it can only survive for an interm ediate range of in uxes. On the one hand, if the in ux is too low, not enough occupied sites are driven out by overstim ulation that holes could lose stability. T hus, the sites occupied in the idealpattem B did not receive the necessary stim ulation and the pattem w as unstable. On the other hand, too high in ux causes $m$ ore and $m$ ore of the frequently occupied vertices to be alm ost perm anently occupied. This but leads to $m$ any stable holes. So, for higher in uxes an abrupt transition to disorder occurs. T he interm ediate behaviour\{ transitions betw een isom orphic con gurations\{ is lacking in this case.

To conchude, we have presented a probabilistic m odel for a local-nule govemed evolution ofoccupied and em pty sites on regular graphs G.A im ing chie y at a description of $\mathbb{N W}$ 's in the imm une system we studied two types of base graphs $G^{(1)}$ and $G^{(2)}$ created by describing idiotypes by bit-strings and their functional interactions by $m$ atching-rules'. In contrast to $m$ ost $m$ odelling approaches to idiotypic netw orks $[\sqrt{1}]$, the m odel abstains from all details of the dynam ics of the real-life interactions of cells, but aim s at understanding principalm echanism s of netw ork form ation.
$O n G{ }^{(1)}$ and $G^{(2)}$ the dynam ics generated by the $w$ indow algorithm leads to organized netw ork structures, which consist of functionally di erent subsets, distinguished, e.g., by their m ean occupancy. O n both types of base graphs for in uxes I sm all com pared to the system size, a m ultitude of such netw ork-pattems has been found. W e developed a notion of pattem-stability and classi ed them as m etastable. For larger in uxes one type ofpattem prevails. In the case of the one-m ism atch graphs $G{ }^{(1)}$ pattems for interm ediate in ux alw ays consist ofan arrangem ent of $2-c$ clusters ofholes and occupied vertices. W e have given a classi cation of these pattems and have described uctuations around an idealpattem structure by a statisticalapproach via defects. For I > $I_{C}$ these $2-$ chustered pattems becom e unstable, and the system starts oscillating betw een periods during which a pattem structure prevails and periods of disorder. Finally, increasing $I$ further, the dynam ics is m arked by random ness and extrem ely short lifetim es. W e elucidated the nature of these transitions.

These 2 -clusters are nothing but the idiotypeantiidiotype pairsw hich have been proposed as onem echanism for the preservation of $m$ em ory of previously encountered antigen ( $T$ he antidiotype represents the internal im age of the antigen 2 a coherent pattem, how ever, leads to an overallm em ory capacity of the netw ork which increases only logarithm ically w ith the system size. $T$ his is clearly insu cient for a real im m une system. The param eter range where the coherent 2 -chuster pattems em erge can therefore not be the working regim e of a healthy im $m$ une system.

It is worthw hile to note that in this regim e (and in all regim es allow ing for $m$ em ory on $G{ }^{(2)}$ ) the netw ork connectivity decreases w ith grow ing sim ulation tim e, i.e. with growing age. This is in accord w ith experim ental observations and was also found in other modelling approaches $\left[\underline{F}_{1}^{1}\right]$. It suggests that the netw orks gradually losing links is an essence of the lim ited range of allow ed vertex-degrees and hence of cross-linking.

O $n$ the $m$ ore densely $w$ ired graphs $G{ }^{(2)}$ cube pattems have been found for an interm ediate range of in uxes. Increasing I beyond a threshold, the system then settles into dynam ic m ultiple-group' pattems. In this regim e, several subsets $S_{j}$ of the base graph $G{ }^{(2)}$ can be dis-
tinguished according to their $m$ ean occupancy. Vertices of these subsets also di er in the structure of the cluster on $t$ which they typically belong to. Two of these subsets form a strongly interconnected core on $t$, to which vertices of the other groups are bound with different strengthes. E ach of the other subsets consists only of singletons and links to the core and som e of the other groups. The core groups have been found to be alw ays rarely populated, the major fraction of the population being typically contained in two of the other groups.
$T$ he structure encountered in this param eter regim e is in very good agreem ent w th general ideas about the topology of $\mathbb{N} W$ 's $[21,2$ core which could correspond to a central part generally believed to exist in $\mathbb{N W}$ 's. Furtherm ore, richely populated non-core groups are in good agreem ent w ith the notion of a peripheral part of $\mathbb{N W}$ 's. Long lifetim es of vertioes belonging to these groups are in accord w the the idea that the peripheralpart of the netw ork is responsible for the preservation of idiotypic $m$ em ory.
$T$ he issue about the in detailw orking of idiotypicm em ory is stillm uch disputed. A part from the intemal im age hypothesis' severalm echnism s are currently known [401 [43] . O ne of these bases on certain cells (folicular dendritic cells) which occasionally exhibit parts of antigen, which is deem ed enough to su ciently stim ulate the com plem entary idiotype \{ allow ing in this way idiotypic m em ory in a single antigen-speci c clone.

D erived from ourm odela new m echanism for idiotypic m em ory seem s possible: $M$ em ory could be retained in a single antigen-speci c clone which is not preferably stim ulated, but occasionally receives stim ulation from the central part of the netw ork and from new complem entary idiotypes from the bone $m$ arrow which serves as a background stim ulus. This m echanism could collaborate w ith antigen presentation by follicular dendritic cells.

Two further issues which follow from the multi-group structure of netw orks in our m odel seem worthw hile to note.

First, during its evolution the system generates a group $S_{1}$ of alw ays suppressed idiotypes. A though the dynam ics of antigens di ers from that of idiotypes, the existence of such a group im plies that there should be a set of antigens against which an individual is im $m$ une $w$ thout ever having been im m unized against. T he actual location of this set is determ ined by encounters w ith other antigens and, chie $y$, by the fortuitous history of the deploym ent ofbone $m$ arrow in ux during early life.

As a second fact, while the num ber of autoantibodies increases [44] the bone $m$ arrow production is know $n$ to decrease w ith grow ing age [42]. H ere, additional to a decline in connectivity till stationarity is reached, our m odel suggests another structural alteration of the network. A ssum ing for young individuals a working point of $\mathbb{N} W$ 's which is above the param eter regim e of singleclone pattems, a decreased bone $m$ arrow production leads to sm aller cores and an increasing periphery, i.e.
an accum ulation ofm em ory and loss of plasticity.
Sum $m$ arizing our $m$ ain result, taking into account different levels of coarse-graining of reaction a nities betw een idiotypes \{as represented by the base graphs $\mathrm{G}_{\mathrm{d}}{ }^{(1)}$ and $G_{d}^{(2)}\{$ leads to two di erent regim es of steady-state behaviours: (i) rigid boherent' con gurations on $G^{(1)}$ and (ii) dynam ic pattems on $\mathrm{G}^{(2)}$ which are increasingly dom inated by 1 -clones. W e con jecture that generally isolated clones are a consequence of a high connectivity of the netw ork and high interaction strength betw een idiotypes. It is suggestive that the bone $m$ arrow in $u x$ is a driving $m$ echanism for shaping the structure of $\mathbb{N} W$ ' $s$, which togetherw ith the interaction strength of idiotypes, determ ines the working point of an $\mathbb{N} W$.

[30] For $t_{1}=0$ the $w$ indow algorithm can be re-form ulated from a holes' point of view. Let $\varrho_{0} v=\quad @ v$ denote the num ber of em pty sites adjacent to a vertex v. A ccording to step (2) of the window algorithm an occupied vertex is taken out if@v $>t_{u}$. T he idea ofstable holes im plies that holes $h$ can only be taken out if $@_{h}=@_{0} h<t_{u}+1$. $T$ hus, holes $h$ can only be rem oved if $@_{0} h>t_{u}^{\text {hole }}=$ $t_{u}+1, w h i c h$ is \{considering tim escales at which holes are probed frequently enough \{ the sam e rule as for occupied vertices.
[31] There are $\begin{aligned} & \text { I } \\ & j\end{aligned}$ variants to choose jout of I vertices which are to be placed in the neighbourhood of a speci ed occupied vertex. Then, since it has a 2 -clusterm ate, $j^{1}$ choiges to distribute these $j$ vertices in this vertex' 1neighbourhood rem ain. T he last factor gives the num ber of ways how the other I j vertices can be distributed on the rem aining $N \quad(1)$ holes of the pattem.

[33] This can be understood as a result of two com peting $m$ echanism $s$. On the one hand, higher tu dem ands less vertices to be taken out in order to $m$ ake a hole unstable. O $n$ the other hand, how ever, the e ort to rem ove a vertex grows w ith $t_{u}$. It can be easily veri ed that the second tendency outw eighs the rst one.
