Speci c Heat of Ce $_1$ $_x La_x R \, h \, In_5$ in Zero and Applied M agnetic Field: A Very R ich Phase D iagram

J.S.K im, J.A lwood, D.M ixson, P.W atts, and G.R. Stewart Department of Physics, University of Florida, Gainesville, Fl. 32611-8440

Abstract: Speci c heat and m agnetization results as a function of eld on single—and poly-crystalline samples of Ce_{1 x}La_xRhIn₅ show 1.) a speci c heat of about 100 m J/m oleK² (in agreement with recent dH vA results of A livers et al.); 2.) uptums at low temperatures in C/T and that tapower law behavior (<=> Gri ths phase non-Fermiliquid behavior); 3.) a eld induced anomaly in C/T as well as M vs H behavior in good agreement with the recent Gri ths phase theory of Castro Neto and Jones, where M ~H at low eld, M ~H above a crossover eld, C/T~T $^{1+}$ at low eld, and C/T~(H $^{2+}$ $^{-2}$ /T $^{3-}$ $^{-2}$)*exp(- $_{\rm eff}$ H/T) above the same crossover eld as determined in the magnetization and where is independently determined from the temperature dependence of at low temperatures, ~T $^{1+}$ and low elds.

I Introduction

Recently, a new family of heavy-ferm ion compounds has been discovered that crystallize in a layered, tetragonal structure with chemical composition CeM In5, where M = Ir, Co, and Rh. Characteristic of heavy-ferm ion systems, each member exhibits a large Sommerfeld coecient (C/T as T!0) in the specicheat C.CeIrIn5 and CeCoIn5 are bulk superconductors $^{1/2}$ with transition temperatures at T $_{\rm C}=0.4$ K and 2.3 K and normal-state values of 750 m J/m oIK 2 and 1200 m J/m oIK 2 , respectively. CeRhIn5 displays heavy-ferm ion antiferrom agnetism with 3 T $_{\rm N}=3.8$ K. A precise value of is dicult to establish unambiguously because of the Neel order; a lower limit of approximately 400 m J/m oIK 2 has been quoted $^{4/5}$.

In our high $\,$ eld speci c heat measurements 6 on the CeM $\rm In_5$ com pounds, we found that the large upturn for M = Rh in C/T above T_N (C/Tis already 1000 m J/m o \mathbb{K}^2 at T_N) as tem perature is lowered appeared to be prim arily due to magnetic interactions above the antiferrom agnetic transition since the specic heat data at a given temperature for $T > T_N$ in dierent elds up to 32 T allocincide with one another when the tem perature axis was scaled to T/T $_{\rm N}$. Recently A liver, et al. have perform ${\rm ed}^7$ dH vA m easurem ents on twelve single crystal sam ples spanning the whole composition range of Ce_{1} $_{x}La_{x}RhIn_{5}$ and nd rather low (i. e. inconsistent by approxim ately an order of magnitude of 400 m J/m olk²) e ective m asses from the dilute Ce, large x end of the phase diagram up to x=0.1. At this Ce-rich end of the composition range they nd an increase in the e ective masses (which still remain which they ascribe to spin uctuation e ects. Alver, et al. conclude that the Ce felectrons remain localized in $Ce_1 \times La_x RhIn_5$ for all x, with the (modest) observed m assenhancem ent near pure CeRhIn5 due to spin uctuation e ects. A lthough com parisons between speci cheat and dH vA data have inherent problems (not the least of which is the possibility of unseen, heavier mass orbits in the dH vA m easurem ents), an e ective m assenhancem ent of approximately ten normally corresponds to a specic heat of only $\sim 50 \text{ m J/m o IK}^2$. This is a wide discrepancy from the estimate of 400 m J/m olk 2 in 4 5 the literature; this discrepancy would be consistent with our high eld speci c heat result 6 that the upturn above T_N in C/T in pure $C \in RhIn_5$ is primarily caused by magnetic interactions, which would not cause a mass enhancement observable, e.g., in dH vA m easurem ents.

In order to help resolve this seem ing disagreement, to determ ine the specicheat (also proportional to the elective mass) in a region of the phase diagram away from the antiferrom agnetic anomaly, and to look for possible new behavior in the dilute limit we report here on a specicheat study of both single and polycrystalline samples of Ce₁ xLa_xRhIn₅, 0 x 0.95. Certainly, doping studies 10 on other heavy Fermion systems, e.g. Ce₁ xLa_xCu₂Si₂, Ce₁ xTh_xCu₂Si₂, and U₁ xTh_xBe₁₃, have revealed interesting new information—both about the respective parent compound as well as new physics in the dilute limit. Polycrystalline samples were originally chosen for the study as being more easily and rapidly prepared. However, specicheat results for polycrystalline

 $C\,e_{1-x}\,L_{a_x}\,R\,h\,In_5$, x=0.5 and 0.8 were determ ined to disagree with speci-c heat results for single crystal samples, while results agreed for x=0.15 and 0.95. This disagreem ent appears due to the presence of a second phase which we were able to eliminate through long term annealing of the polycrystalline samples at a relatively low temperature.

II Experim ental

Single crystalsam ples of Ce_{1} x $La_{x}RhIn_{5}$ were prepared using the procedure described in ref. 6, which was similar to that used in refs. 4 and 7. Excess In was removed from the resulting at platelet crystals using an H₂O HF H₂O₂ 411 etch which was dierent than the centrifigalm ethod (H2O HCl41 etch) used in ref. 4 (7); however the present work's speci c heat results (which are a measure of bulk properties) should be relatively independent of such surface treatments. The polycrystalline samples in the present work (previous work in the literature has been almost uniform by on single crystal samples) were prepared by melting together stoichiom etric amounts of the appropriate high purity starting elements (using Ames Laboratory Ce and La, 99.95% pure Rh from Johnson Mathey Aesar, and 99.9999% In from Johnson Matthey Aesar - the same starting materials as used for the single crystals) under a puri ed inert Aratmosphere. Weight losses after four melts, with a ipping of the arcm elted button between m elts to im prove hom ogeneity, were in the range of 1%, prim arily due to In loss. Additional In was added in the beginning to correct for this, such that the In concentrations after the last melt were within 02% of the stoichiom etric am ount.

Speci cheat in elds to 13 T were measured using established techniques 11 , while magnetic susceptibility data were measured in a SQUID magnetometer from Quantum Design.

III R esults and D iscussion

Figure 1 shows the speci c heat divided by tem perature vs tem perature for single crystal Ce $_{\rm 1-x}La_{\rm x}RhIn_{\rm 5}$, x=0,0.15,0.5,0.8, and 0.95 and polycrystal Ce $_{\rm 1-x}La_{\rm x}RhIn_{\rm 5}$, x=0.32. All sam ples were single phase. Results for unannealed polycrystalline Ce $_{\rm 1-x}La_{\rm x}RhIn_{\rm 5}$, x=0.15 and 0.95, and annealed (35 days at 720 °C) polycrystalline Ce $_{\rm 1-x}La_{\rm x}RhIn_{\rm 5}$, x=0.5 and 0.8, were comparable to the single crystal results (see inset of Fig. 1 for an example); however, unannealed polycrystalline samples for x=0.5 and 0.8 contained a second phase that ordered antiferrom agnetically below 1 K . This was taken as a sign of an incipient m is cibility gap which -due to previous work being focussed on single crystal samples -was heretofore unknown.

From the data shown in Fig. 1, one can follow the suppression of the antiferrom agnetic transition with increasing La doping; there is a clear, although reduced in magnitude, transition at 2 K for 15% La doping that is absent by x=0.32. Although one might expect 12 non-Fermi liquid ('nF1') behavior when $T_{\rm N}$ is suppressed to T=0, the temperature dependence of the C/T data for

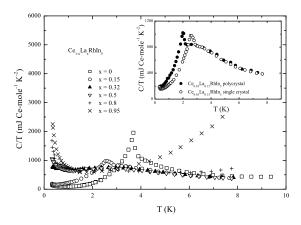

Figure 1: C/T vs T for Ce(1-x)La(x)RhIn(5)

x=0.32 -although the

data show an upturm - is only m easured for $\sim 0.5 \, \text{K}$ below the hum p. This is too restricted a tem perature range to allow conclusions about the tem perature dependence.

Before we discuss the behavior of as a function of x in Ce $_{x}$ La $_{x}$ R hIn $_{5}$, we will rst focus on the upturn at low tem peratures for x 0.5.

A Upturn in C/T for x 0.5

The upturn in C/T for x 0.5 in Ce_{1 x}La_xRhIn₅ shown in Figs. 1 is t in Figs. 2 and 3 for single crystalline, as well as single phase polycrystalline, m aterial. Note in Fig. 2 that the data for the three di erent samples agree rather well. There is certainly no sign in the dH vA results of A liver, et al. for a strong, heavy ferm ion upturn in C/T that would cause large e ective m asses. Thus, this upturn at low tem peratures in C/T likely has a magnetic interaction explanation (see section C below for the eld dependence). The temperature dependence of the upturns in C/T (see Figs. 2 and 3) for single crystal $Ce_1 \times La_x RhIn_5$, x=0.5, 0.8, and 0.95, is not at all like the high tem perature side of a Schottky peak (C $\sim 1/T^2$) but rather appears (in the som ew hat lim ited tem perature range that we have data) to follow C/T \sim T $^{-1+}$, $_{\text{C/T}} = 0.63$ 0.1, 0.1, and ~0 respectively. This is the temperature dependence predicted for non-Ferm i liquid behavior caused by disorder-induced spin clusters, the socalled G ri ths phase 12 13 . (Note that the ts of to T $^{1+}$ below 1.2 K are much better than ts to either log T or T 0:5.) In this theory, the magnetic susceptibility

at low temperature should have the same power law dependence as ${\rm C}/{\rm T}$. The susceptibility at low temperatures for these same compositions of single

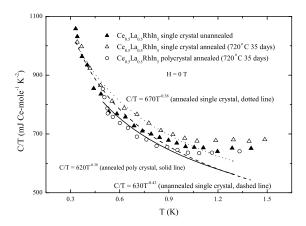

Figure 2: C/T for 3 sam ples of x = 0.5

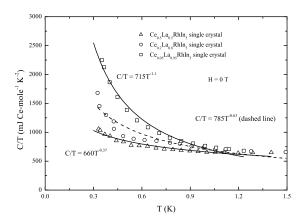

Figure 3: C/T vs T, x=0.5,0.8,0.95, t to T^(-1+ lam bda)

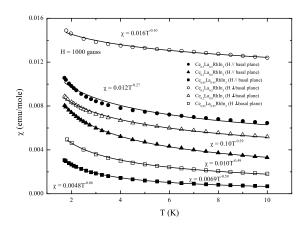

Figure 4: Chivs T tto T^(-1+ lam bda)

crystal Ce_{1} x $La_{x}RhIn_{5}$, see Fig. 4, does indeed t this T^{-1+} dependence, with = f0.73,0.90g, f0.50,0.70g, f0.14,0.30g respectively for H f?, kg the c-axis, where the absolute error bar for each value is 0.1 (with, how ever, som ew hat better precision, useful for intercom parison between values derived from a given measurement technique. For example, 0.14 derived from for x= 0.95 is certainly less than 0.30 derived for the other eld direction, but is com parable to the value of ~0 derived for the same composition from the specic heat.) (Note that other standard non-Ferm i liquid temperature dependences, such as $\sim \log T$ or $T^{0.5}$, do not the data at all well.) Although for a given composition the respective exponents for C/T and agree within experiment accuracy only for (H ? c), the recent theory 14 of Castro Neto and Jones actually predicts that and C/T may diverge dierently at low temperature, relaxing the requirem ent of the early theory 12 13 that 2 2 2 . It is clear that the disorder requirem ent for uncompensated spins (which requires that M vs H is shows saturation behavior) is full led for all these compositions (see discussion and accompanying gures in section C below.) In addition, the agreement in $_{C=T}$ and found for the upturn in C/T and in the present work is comparable to that found by, e. q., deAndrade et al. in their study of Th_{1 x}U_xPd₂A \lg - even though they measured down to 0.5 K, i. e. in a tem perature range com parable to that for their speci c heat m easurem ents. The anisotropy of the susceptibility-determ ined values is thought to be real, and not related to the discrepancy between C=T and

As one possible check for a tendency towards magnetic behavior, the W ilson ratio (R / / $_{\rm eff}^2$) -which is used 16 in the study of heavy Ferm ion systems to track the tendency towards magnetism, with R % 0.8 indicating 16 magnetic behavior-for these Ce $_{\rm l}$ $_{\rm x} {\rm La}_{\rm x} {\rm R} \, h \, {\rm In}_5$ alloys is in the range of 1.0 to 1.8, i. e. they de nitely show magnetic character. As a further check for evidence

for spin clusters, we investigated these compositions for spin glass behavior and to within the limits (2%) of the accuracy of the measurements – found no dierence between eld cooled and zero eld cooled data down to 1.8 K . This lack of observable spin glass behavior in the dcm agnetic susceptibility in these samples does not rule out a G ri ths phase interpretation 17 .

B Speci c Heat as a Function of x

The original goal of this work, besides the hope for new physics of interest in the dilute range (already partially fulled by the results discussed above for the low temperature uptum in C/T and) was to investigate the specic heat (de ned as C/T as T!0) away from the region of the phase diagram where antiferrom agnetism obscures C/T as T!0 in CeRhIn $_{\rm 5}$ diluted with La. As discussed above, after the antiferrom agnetism is suppressed (x>0.15), a low temperature uptum in the C/T data (Fig. 1) occurs that, normalized per Cemole, becomes more pronounced with increasing dilution of the Ce. This uptum appears not to be related to the elective masses measured by the dH vA measurements.

A further complication to determining the specic heat is the rounded feature in C/T centered at ~3 K visible already for x=0.15 above T_N . As may be seen from Fig. 5, the C/T data for x=0.5 (triangles) and 0.8 (circles) in Ce_{l} $_{x}La_{x}RhIn_{5}$ above the low tem perature upturn show a tendency to curve or bend downwards down to about 1.5 K, at which point the upturn discussed in the section above begins. This 'hum p' in C/T centered at ~3 K m akes extrapolating C/T to T=0 to determ ine a som ew hat in precise procedure. It should be stressed that this rounded feature, or hump, in C/T has its provenance in the f-electron sublattice: such a feature is not present in C/T data for pure LaR h In 18. One possibility for correcting for this feature in order to determ ine is to subtract o both the low temperature upturn (see Fig. 3 for the ts to the uptums) and a t^{18} to pure LaRhIn₅ and exam ine the remainder. As shown in the inset to Fig. 5 for x=0.5, this very rough approximation (the apparent negative value below about 1 K is, see Fig. 3, m erely a sign that the t to the upturm – which goes up to over 1000 m $\mbox{J/C}\,\mbox{e-m}\,\mbox{ole}\mbox{K}^{\,2}$ at 0.3 K – is in error as T! 1 K) allows us to assign an approximate value per Cem ole of 100 m J/C em olK 2 for x 0.5. This agrees much better with Alver, et al.'s dH vA results than the estim ates of 400 m J/C em olK 2 estim ated 4 5 in the literature. However, as the La dilution is removed, for x 0.1, A lver, et al. report approximately a factor of two increase in elective mass due to spin uctuation e ects, with an e ective mass for pure CeRhIn5 that would correspond to a of approximately 50 m J/C em olK2. In the dilute limit, A liver et al.'s e ective m easured e ective m ass corresponds to a of only 25 m J/C em olk 2. However, as may be seen in Fig. 5, our C/T data at low temperature are much too obscured by the unexpected upturn as well as by the rounded maximum to supply any sort of accurate estimate for beyond the dilute, x 0.5, range of 100 m J/C em olK 2 already quoted above.

C Field Induced Anomaly for x 0.5
As a nalaspect of new, unexpected behavior for CeRhIn₅ diluted with

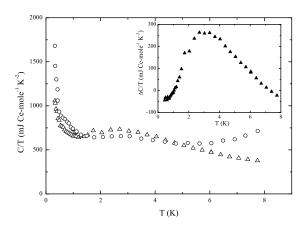

Figure 5: C/T vs T showing the 'hump' at 3 K

La, when we were investigating the eld dependence of the upturn in the specic heat divided by tem perature using magnetic eld as a probe, we discovered that applied eld suppresses the low tem perature upturn in C/T at rather low eld and induces an peak in C/T that, with increasing eld, moves up in tem perature and becomes broader and less pronounced. This rounded anomaly, shown in Fig. 6 for x=0.95 (these data are typical of the results for all x=0.95) with eld in the basal plane (data in the perpendicular direction are within 15 percent of these), is not that of either a spin glass (where $C\sim1/T$ above the peak) or a Schottky anomaly ($C\sim1/T^2$ above the peak) but rather seems to be a eld-induced anomaly. (The upturns in C/T for H=6 T are caused by the applied eld splitting the nuclear magnetic moment energy levels and creating a Schottky peak in the specic heat.)

Castro N eto and Jones have recently published 14 a theory of how the speci c heat and magnetization of materials with non-Fermi liquid behavior caused by disorder-induced G ri ths phase spin clusters should scale with magnetic eld. In general, both the magnetization and speci cheat are predicted to exhibit low eld behaviors (M $^{\rm H}$ and C/T $^{\rm T}$ $^{1+}$) which crossover over to the respective high eld behaviors (M $^{\rm H}$ and C/T $^{\rm C}$ (H $^{2+}$ = 2 /T $^{3-}$ = 2)e $^{\rm eff\,H\,H\,H}$) at the same magnetic eld. The prediction for the eld and temperature dependence for the high eld speci cheat leads to a peak in C/T (or a shoulder in C) as a function of increasing temperature – thus qualitatively consistent with the data shown in Fig. 6.

Although the speci cheat data in eldwastaken in fairly widely spaced elds, the fact that a peak occurs already in C/T in $H=3\,T$ o ers a prediction (the equality of the crossover eld requires that the crossover eld for the magnetization data be perforce below $3\,T$) that can be checked by examining the M vs H data, where a much more nely spaced sequence of elds was used. In

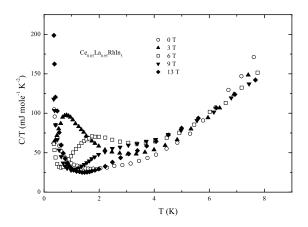

Figure 6: Field-induced anomaly in C/T for x=0.95

addition, the high $\,$ eld prediction that M $\,$ ~H $\,$ can be checked up to 5.5 T, and this eld-dependence determ ination of can then be compared with that independently determined from the temperature dependence of in Figure 4. Thus, m agnetization data for both eld directions for single crystal Ce_{0.05} La_{0.95}R hIn₅ are shown tted to these Griths phase low and high eld predictions in Figures 7 and 8, H k,? basal plane respectively. As may be seen, using the values for determined from Fig. 4 (0.14 and 0.41 for H (k,?) baselplane respectively) gives rather good²⁰ agreem ent between the predicted, M ~H dependence and the high eld magnetization data. (The t to the higher eld data with the low est standard deviation actually gives = 0.67; how ever, the standard deviations are within 8% of one another.) Further, the deviation from linear behavior at low elds occurs (see Figs. 7 and 8) above 0.8 T and the deviation from the M \sim H power law occurs below 12 T. These estimates for the crossover eld are not inconsistent with the peak in C/T (where a peak is characteristic of the high eld regime) occurring in 3 T, Fig. 6. (Work under way²¹ to more thoroughly characterize the low and high eld behavior for M and C/T for x=0.95has found that a peak in C/T eld data taken in 0.5 T increments down to 0.3K rst appears at 1.5 T.)

A nother prediction 14 of the G ri ths phase theory of C astro N eto and Jones, the eld and tem perature dependence of C/T in the high eld limit, is compared 22 to the 3T Ce $_{0:05} \rm La_{0:95} R h In_5$ data (with the t^{18} to pure LaR h In $_5$ and the small, < 10% at the lowest tem perature, contribution due to the eld splitting of the nuclear moments, subtracted o), H k basal plane, in Fig. 9. U sing only two t parameters (the amplitude and the elective moment, eff) and xing = 0.14 (based on) gives the t (dashed line in Fig. 9) as shown, with the reasonable $^{14;23}$ tted value for eff (which corresponds to the average

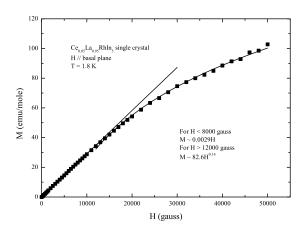

Figure 7: M vs H for x=0.95, H in basalplane

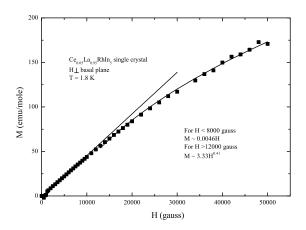

Figure 8: M vs H for x= 0.95, H perp. to basalplane

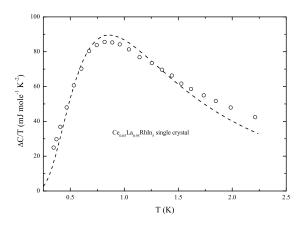

Figure 9: Fit of eld-induced anomaly to theory

m om ent in the G ri ths phase spin cluster) of $1.25~_{\rm B}$. C learly, tting C/T to (H $^{2+}$ = 2 /T 3 = 2)e $^{\rm eff\,H}$ =T is a fairly good representation of the data. (To give an idea how the t depends on the elective moment, a t to these 3 T data with $^{\rm eff}$ constrained to be 1.0 $^{\rm B}$ is shifted by to lower temperatures by $^{\rm c}$ 0.2 K from the present t.)

IV Conclusions

Despite the diculty of precisely compensating for the broad peak in C/T in Ce_{1} $_{x}La_{x}RhIn_{5}$ centered at about 3 K, the apparent per Cemolefor x 0.5, away from the antiferrom agnetic transition in the phase diagram, appears to be less than 100 m J/C e-m oleK 2 - in disagreem ent with estim ates for in the literature but not inconsistent with the dH vA results of A livers et al. There is a strong upturn in C/T below 1 K for x 0.5 that, when compared to the temperature dependence of the susceptibility and the non-linear M vs H data, is consistent with non-Ferm i liquid behavior due to disordered spin clusters ('G ri the phases.') Applied magnetic eld suppresses this upturm in C/T already by 3 T; above 3 T the C/T results show a broad anomaly that further broadens and moves to higher temperatures as eld is increased. This eld induced anomaly, together with the eld dependence of the magnetization, com pares well with the predictions of the G ri ths phase theory $^{14;24}$ of C astro N eto and Jones, particularly in the magnetization data as a function of eld and the agreem ent of these data with the predicted exponent from the temperature dependence of the susceptibility. In sum mary, the breadth of behavior observed in Ce_{1 x}La_xRhIn₅ in zero and applied eld is indicative of a phase diagram of unusual richness and variety.

A cknow ledgem ents: The authors wish to thank Antonio Castro Neto for quite fruitful discussions. Work at the University of Florida by perform ed

- 22. Fits to the 6 and 9 T data are similar, although the correction for the low temperature upturn in C/T caused by the nuclear hyper nelevel splitting due to the applied eld is larger and the size of the eld-induced anomaly in C/T with increasing eld is rapidly decreasing. Since the crossover eld between low and high eld dependences, as determined by the magnetization, is ~ 0.8 –1.2 T, the 3 T data should be well in the high eld limit.
