Abstract

A new method for preparation of single crystals of the superconducting intermetallic MgB₂ compound from a Mg-Cu-B melt flux is presented. The high vapour pressure of Mg at elevated temperature is a serious challenge of the preparation process. The approximate thermodynamic calculations of the ternary Mg-Cu-B phase diagram show a beneficial effect of Cu, which extends the range of formation of MgB₂ to lower temperatures. Within the as-solidified Mg-Cu-B melt flux the MgB₂ compound forms plate-like single crystals up to a size of 0.2 × 0.2 × 0.05 mm³ or alternatively rims peritectically grown around MgB₄ particles. AC-susceptibility measurements were conducted with specimen selected from different parts of the as-solidified flux containing MgB₂ particles. Peritectically formed MgB₂-particles display the highest transition temperature of T_c = 39.2 K and a relatively narrow transition width of $\Delta T_c = 1.3$ K. Other sections of the sample exhibit various superconducting transitions from T_c = 39 K to 7.2 K. This variation of T_c is attributed to a finite homogeneity range of the MgB₂ compound whereas significant Cu solid solubility in MgB₂ can be excluded.

1. Introduction

The recent discovery of superconductivity of the intermetallic compound MgB₂ [1] has aroused a flurry of theoretical and experimental work [2, 3, 4, 5, 6]. With $T_c = 39$ K, MgB₂ exhibits the highest superconducting transition temperature of intermetallic compounds, which is nearly twice as high as the top T_c values of A15 compounds (Nb₃Ge: $T_c = 23.2$ K) and Rare Earth-Transition Metal-Borocarbides (YPd₂B₂C: $T_c = 23$ K). Only the ceramic oxide superconductors and compounds based on C₆₀ exceed these T_c value [7].

Many important parameters of MgB₂ have already been derived, such as the upper critical field $(H_{c2} = 13 - 20.4 \text{ T})$ [2, 3], the Ginzburg-Landau parameter (k ≈ 26) [3] and the bulk critical superconducting current density ($j_c = 8 \cdot 10^4 \text{ Acm}^2$ at 4.2 K and 12 T) [4] in thin films. The mechanism of superconductivity in MgB₂ is still an open question. Many experiments support the view that MgB₂ is a phonon-mediated superconductor in the weak- to moderate-coupling regime [5]. On the other hand it is proposed that the theory of hole superconductivity may also account for MgB₂ [6]. Experimental data that can shed light on its synthesis, doping, phase formation and the phase equilibria in this system are of great interest. One of the surprising features of superconducting MgB₂ is the simplicity of both its chemistry and structure. MgB₂ crystallizes in the AlB₂ crystal structure where honeycomb layers of boron atoms alternate with hexagonal layers of Mg atoms. The lattice parameters are a = 0.30834 nm and c = 0.35213 nm [8]. But the very limited substitutional chemistry [9,10,11] possibly suggests that the structure may be more complex than on a first glance.

Although this material is available from common chemical suppliers and has been characterized since the mid 1950s, up to now the investigations are basically limited to polycrystalline samples and thin films [4]. Ceramic samples were successfully prepared by ambient pressure synthesis in sealed Ta or Mo crucibles [3,12], but more dense ceramic was obtained by hot isostatic pressing at 950°C under pressure of several GPa of boron and magnesium powders as starting materials [1,13]. There were great efforts in doping of MgB₂ [14,15]. There is also an idea of a finite homogeneity range of MgB₂ compound. A higher T_c is expected if the composition is on the B-rich side [16], which is in accord with the very low $T_c = 12$ K of Mg-rich films [17]. Only recently growth of MgB₂ single crystals with maximum size $0.5 \times 0.5 \times 0.02$ mm³ has been achieved using a vapour transport method [18]. The crystals show a relatively gradual superconducting transition with an onset temperature of 38.6 K. Growth from the melt, which can in principle lead to larger sized crystals, is aggravated by the high vapour pressure of Mg. To our knowledge, there was no successful attempt of MgB₂ crystal growth from Mg-B melts so far.

In this work, a new method of MgB₂ crystal growth from the Mg-Cu-B flux is presented. The reasons for the choice of Cu as a solvent for B and Mg are: (i) large solubility of boron in the Cu-B melt at least 13.3 at.% at the eutectic temperature 1013°C, (ii) absence of binary Cu-B [19] or ternary Mg-Cu-B intermetallic compounds and improbable doping of MgB₂ with Cu because of the high affinity of Cu and Mg to form intermetallic compounds [14] (iii) facilitated crystallization of desired refractory magnesium borides in Mg-Cu-B because of low melting temperatures (< 800°C) of remaining binary compounds. Our experimental trials are supported by approximate thermodynamic calculations of the ternary Mg-Cu-B phase diagram, which are based on existing thermodynamic data of binary systems. The phase diagram data served as a guideline for optimizing process parameters of crystallization and interpretation of various microstructures observed in Mg-Cu-B fluxes in a wide composition range. The results of measurements of superconducting properties of Mg-Cu-B samples containing MgB₂ crystals with different morphologies are presented.

2. Experimental methods

2.1. Crystal growth procedure

The Mg-Cu-B flux was prepared from Cu (99.99%), Mg (99.9%) powders (or cheeps) and commercial MgB₂ powder (Alfa Aesar) as a source of boron. Using MgB₂ powder is superior with respect to pure amorphous boron due to its higher reactivity with the melt, smaller grain size and higher purity (especially: the low oxygen content). This finally resulted in a much higher rate of

the dissolution in the melt. The starting materials were weighted in a desired ratio, mixed and

pressed into pellets of 20 mm in length and 8 mm in diameter under a protective Ar atmosphere to prevent oxidation and contamination. Melting and crystallization experiments were conducted with an experimental setup, which enables simultaneous processing of Mg-Cu-B fluxes with different composition. Bars of various compositions were inserted into a graphite crucible and separated by graphite disks from each other (see Fig. 1). Before melting, the graphite crucible was inserted into stainless steel containment with 1 mm wall thickness, which was evacuated, backfilled with He and sealed to prevent Mg evaporation and maintain Mg vapour pressure at equilibrium conditions. The experimental arrangement was close to that used for Mg₂Si single crystal growth reported by LaBotz and Mason [20] (see also [21]). The closed containment was installed into a tube furnace heated with 250 K/h and homogenized at a constant temperature for 20 to 50 hours. Annealing temperatures from $T_0 = 900^{\circ}$ C to 1350°C were selected for various runs. For crystallization the samples were slowly cooled down to room temperature with 5 K/h to 200 K/h. In order to avoid reactions between graphite and stainless steel at temperatures higher than 1100°C a Ta-foil was placed between the two crucible materials. The absence of any chemical reaction between the melted Mg-Cu-B flux and the graphite crucible was confirmed afterwards.

2.2 Sample characterization

The frozen samples were cut along the cylinder axis. The longitudinal sections were grinded and polished. A longitudinal section of the graphite crucible containing crystallized Mg-Cu-B samples of various compositions is shown in Fig. 1. The microstructure was revealed by optical metallography and scanning electron microscopy (SEM). Compositions of selected phases were determined by electron probe microanalysis (EPMA) applying the WDX mode. Specimens of 1×1 $\times 1$ mm³ size containing magnesium boride crystals of different composition and morphology were cut from the frozen flux. Superconducting properties of these specimens were determined from AC-susceptibility measurements at 133 Hz and an AC-field amplitude of 1 Oe in the temperature range 5 to 55 K using both a Lakeshore model 7225 AC susceptometer and a susceptometer from the Institute of Solid State Physics RAS, Chernogolovka.

3. Results and discussions

3.1. Mg-Cu-B phase diagram

The equilibrium phase diagram of the Mg-B binary system has not been reliably determined. The phase relations strongly depend on the Mg vapour pressure [22, 23, 24]. In particular, the MgB₂ phase decomposes at about 1090°C under 0.1 MPa of Mg vapour pressure. Only in the low temperature range from 650°C to 1090°C the MgB₂ phase may coexist with a Mg-rich melt. The Cu-B phase diagram is of simple eutectic type with no intermediate phases [22]. The maximum solubility of B in the solid Cu is about 0.3 at.%. The phase diagram of the Cu-Mg system is well established [22]. There are three eutectics and two congruently melting compounds Mg₂Cu and MgCu₂. The solubility of Cu in Mg is restricted to 0.013 at.% Cu. The stoichiometric compound Mg₂Cu melts at 568 °C. The nonstoichiometric compound MgCu₂ melts congruently at 797 °C and has a maximum homogeneity range of about 64.7 to 69 at.% Cu. The maximum solid solubility of Mg in Cu is 6.93 at.% Mg. No ternary Mg-Cu-B phase diagram is available so far.

3.2. Thermodynamic calculations

In order to get a first idea of the possible phase equilibria, thermodynamic calculations based on the binary subsystems and on the assumption that no ternary compounds exist were carried out using the multicomponent phase diagram calculation software PANDAT [25]. The thermodynamic descriptions of the binary systems Mg-B and Cu-Mg were taken from the literature [24, 26]. The parameters for the B-Cu system were obtained empirically in order to reproduce the literature data on invariant equilibria and terminal solubilities by calculations in this work. In the binary Mg-B system the calculations showed that the coexistence range of liquid and MgB₂ is extended towards higher temperature with rising pressure and at pressures exceeding 8 MPa the MgB₂ phase may even form directly from a Mg-rich melt via a peritectic reaction.

The first comparison of the calculated ternary phase diagram with the experimental results showed, that it is necessary to adjust the Gibbs energy description of MgB_2 phase as well as to take ternary interactions in the liquid phase into account. Owing to insufficient and sometimes contradictory thermodynamic data for binary Mg-B compounds [24], a more positive value (-60 kJ/mol) was proposed for the enthalpy of formation of MgB₂. This only results in a depression of the decomposition temperature of this compound, which has never been determined experimentally, by about 200 K. At the same time, it is in agreement with the location of fields of primary crystallization determined in the present work (see below). To estimate the behaviour of the ternary Mg-Cu-B melt calculations were performed for two limiting cases: weak interaction (Fig. 2a) and very strong interaction (Fig. 2b). Due to the limited amount of experimental data obtained in this work, the optimization of the corresponding ternary interaction parameter was not possible. Under the experimental conditions applied the solidification of the flux proceeds at elevated pressure within the sealed container. However, the Mg vapour pressure within the container is not a fixed quantity, which can be controlled properly, but it depends on the operating temperature ($P \sim 0.2$ MPa for 1000°C). Therefore, the projections of liquidus surface were calculated at infinitely high pressure, i.e., by excluding the gas phase from consideration. However, some general tendencies, which can be helpful for the crystal growth experiments, may be inferred. The calculations show that the crystallization range of MgB₂ (and of the other binary phases MgB₄ and MgB₇) has a great extent into the ternary Mg-Cu-B system. The temperatures of MgB₂ formation are gradually reduced with increasing Cu-fraction (cf. Fig. 2a). In the case of very strong interaction the ternary system exhibits miscibility gaps near the Mg-, Cu- and B-corners, respectively. In Fig. 2b a projection of a liquidus surface is shown, which displays both the extent of the crystallization range of MgB₂ and the miscibility gaps of the melt. The various Mg-Cu-B flux compositions treated in our experiments are indicated by various dots in Fig. 2.

3.3. Microstructure of as-solidified samples

Depending on melt composition and initial temperature of the melt T_0 , as-solidified samples contain the following phases: Mg and Cu metals, the intermetallic compounds MgCu₂ and Mg₂Cu as well as small crystallites of Mg-borides - MgB₂, MgB₄ and MgB₇. Flux compositions (up to 50 at.% Cu) containing the superconducting MgB₂ phase in the as-solidified state are displayed in Fig. 2. No ternary Mg-Cu-B compounds were detected. The Mg-boride crystals exhibit sharply-edged geometric shapes and a dark colour and can easily be identified on the golden or silver background of the Mg-Cu flux. However, because B and Mg are light elements it is very difficult to distinguish the various Mg-borides - MgB₂, MgB₄ and MgB₇- from EPMA even by employing the WDX technique. In this respect the optical metallography offers great advantages. Crystals of MgB₂ possess strongly anisotropic characteristics of polarized light reflection and they become hardly bright if polarisation is changed. Crystals of MgB₇ display anisotropic properties with respect to polarized light in much less extent whereas for MgB₄ crystals almost no optical anisotropy was observed.

Besides the flux composition, the initial melt temperature T_0 before slow cooling turned out as the decisive parameter for the formation of Mg-borides. For high temperatures ($T_0 > 1100^{\circ}$ C) the formation of MgB₄ and MgB₇ prevails and no MgB₂ was formed. Typical microstructures of a Mg₃₀Cu₅₀B₂₀ flux cooled by 5 K/h from 1200°C containing non-superconducting MgB₇ and MgB₄ precipitates are shown in Fig. 3. The MgB₇ particles display a plate-like shape with typical dimensions $350 \times 350 \times 50 \ \mu\text{m}^3$. The MgB₄ particles tend to be equiaxed sharply edged grains up to 500 μm in size.

At temperatures below $T_0 \approx 1100^{\circ}$ C for the same Mg₃₀Cu₅₀B₂₀ melt composition the MgB₂ phase can be formed peritectically as a rim surrounding the MgB₄ primary phase as demonstrated in Fig. 4a. That confirms that the theoretically predicted peritectic reaction

$L + MgB_4 \rightarrow MgB_2$

at elevated pressure indeed proceeds for ternary Mg-Cu-B alloys. So far, the peritectic formation of MgB₂ was not observed. If the initial melt temperatures were below 1100°C, for melt compositions in the range Mg₈₀₋₃₀Cu₁₀₋₅₀B₁₀₋₂₀ (*cf.* Fig. 2), the MgB₂ phase is primarily crystallized from the Mg-Cu-B flux. As shown in Fig. 4b and 4c the MgB₂ crystals appear as thin plates and their sizes strongly depend on melt composition and temperature course. The maximum size of the crystal achieved is about $200 \times 200 \times 50 \ \mu\text{m}^3$ for the optimum process conditions (Mg₅₀Cu₄₀B₁₀, $T_0 \approx 1050^{\circ}$ C, and cooling rate 5 K/h). The absence of any grain boundaries within the MgB₂ particles are incorporated within the matrix of MgB₂ crystals. They probably act as seeds for the generation of new MgB₂ crystals and strongly reduce the maximum crystal size. So far we have not found appropriate techniques to get rid of solid Mg-oxide in the Mg-Cu-B melt.

For Mg-rich flux compositions with < 30 at.% Cu a phase separation of the melt into Mg-rich and Cu-rich regions was inferred from the microstructure. This is illustrated in Fig. 5 for a Mg₇₀Cu₁₀B₂₀ flux. There is an obvious tendency of forming Mg-rich regions with a high density of small MgB₂ particles separated by a Cu-rich flux containing larger MgB₂ particles with lower particle number density. Seemingly, this microstructure arises from a miscibility gap in the Mg-rich corner as predicted by the Mg-Cu-B phase diagram calculation shown in Fig. 2b. The concentration range for phase separation phenomena observed in microstructures does not quantitatively agree with the predicted miscibility gap but extends toward somewhat higher Cu contents.

In agreement with thermodynamic calculations our experimental observations suggest that the vapour pressure of Mg must have a great influence on MgB₂ phase formation from the melt. Any attempt of directional solidification of Mg-Cu-B melts in a finite temperature gradient (30 K/cm) failed to form MgB₂, instead the MgB₄ phase was obtained. We interpret this failure as a result of the lower temperature at cooled side of the sealed container, which may cause sublimation of the Mg vapour. This would immediately result in a reduced equilibrium Mg vapour pressure in the

ampoule and finally, in the decomposition of the MgB_2 phase within the Mg-Cu-B melt flux. That renders the operating window of MgB_2 phase formation from the Mg-Cu-B melt flux extremely narrow.

3.3 Superconducting properties

Superconducting properties have been measured for a wide composition range of $Mg_{80-30}Cu_{10}$. $_{50}B_{10-20}$ flux bars containing MgB₂ particles. Within the Mg-Cu-B system only the MgB₂ phase is known to display superconducting properties with $T_c > 4.2$ K. That strongly simplifies the data analysis of superconductivity measurements. The superconducting behaviour detected in bulk samples originate from MgB₂ particles crystallized from the molten Mg-Cu-B flux. All flux compositions which exhibit no superconducting properties are indicated by open dots in Fig. 2. No traces of unreacted MgB₂ powder from the starting materials have been detected, which might have contributed to the superconducting behaviour. For great excess of boron (> 20 at.% B) in the flux composition MgB₄ particles have been detected, which have not been precipitated from the melt but are likely the result of MgB₂-powder decomposition processes during heating.

Typical AC susceptibility vs. temperature plots c(T) are shown in Fig. 6. No superconductivity beyond 4.2 K has been detected in specimens without macroscopically visible MgB₂ particles. The largest superconducting transition temperature $T_c = 39.2$ K and the narrowest transition width DT_c = 1.3 K (from 90% to 10% of c(T)) have been observed in Mg-Cu-B specimens containing MgB₂ particles formed by a peritectic reaction from the MgB₄ phase (cf. Fig. 4a). This phase formation mode was found for Cu-rich fluxes (Mg₃₀Cu₅₀B₂₀) and annealing temperatures $T_0 \approx 1100^{\circ}$ C. The cooling rate plays a minor role in the superconducting phase formation. Flux compositions in the range of Mg₈₀₋₄₀Cu₁₀₋₄₀B₁₀₋₂₀ with plate-like MgB₂ crystals primarily formed at liquidus temperatures below the peritectic point, exhibit superconducting transitions at lower T_c possibly depending on the temperature of formation of the MgB₂ phase. As shown in Fig. 6, typically, two subsequent superconducting transitions have been inferred from the measurements for Mg-rich flux compositions in the vicinity of the predicted miscibility gap (*cf.* Fig. 2b). The sample $Mg_{60}Cu_{30}B_{10}$ (1) with small B-concentration displays two transitions with low onset temperatures $T_{c1} \approx 22$ K and $T_{c2} =$ 7.2. For various specimens along an isoplethal section at 20 at.% B from 70 to 50 at.% Mg we derived $T_{c1} \approx 39$ K and a very distinct second transition at T_{c2} , which slopes down from 31 to 27 K with increasing Cu-content of the flux from 10 to 30 at.%. But for $Mg_{40}Cu_{40}B_{20}$ the second transition practically disappears, which gives rise to a smooth transition similar to that of crystals prepared by vapour deposition [18].

The possible effect of Cu solubility on superconducting properties of MgB₂ [14,15] was revealed by EPMA analysis. No trace of Cu has been detected in MgB₂ particles. Therefore we can rule out any Cu-solubility in MgB₂ within the accuracy limits of the WDX analysis (< 1 at.%). The high onset temperature $T_{c1} \approx 39$ K itself excludes sizeable Cu solubility because of the reported depression of T_c by 0.2 K/mol.% Cu [14]. The existence of a finite homogeneity region of MgB₂. compound is assumed to explain the variation of superconducting transition temperatures T_c . This is already suggested by the large transition width of the order of $DT_c \sim 10$ K of crystals prepared by vapour deposition [18]. The highest T_c was achieved for the peritectically formed MgB₂ that is assumed to possess a composition close to stoichiometry. The smaller temperature of formation of the MgB₂ crystals the larger is the deviation from stoichiometry, accordingly resulting in lower T_c . The two very distinct superconducting transitions in phase separated samples hint to growth processes proceeding at different temperatures within the Mg- and the Cu-enriched flux regions, respectively, and accordingly to different compositions of the individual MgB₂ crystals. A particularly, low T_c is achieved in the Mg₆₀Cu₃₀B₁₀ sample with low B-concentration which may lead to B-depletion in MgB₂ crystals. Our suggestion also coincides with conclusions from superconducting measurements of ceramic MgB₂ samples [16] and on Mg-enriched MgB₂ films with very low T_c =12 K [17].

4. Conclusions

A new method is presented for growth of MgB₂ crystals from Mg-Cu-B melt flux. Large solubility of > 20 at.% B in the Mg-Cu melt at temperatures > 1000°C, depending on melt composition, have been found. First estimates of ternary Mg-Cu-B phase diagram by thermodynamic calculations show the beneficial effect of Cu and elevated pressure on MgB₂ phase formation. Unlike the binary Mg-B system, MgB₂ phase formation from the melt is enabled by reducing the liquidus temperature. The theoretically predicted phase separation phenomena in the Mg-rich region has been observed experimentally. The size of the MgB₂ crystals strongly depends on melt composition and initial melt temperature T_0 . Although not quantified the elevated pressure within the sealed container seems to be indispensable for MgB₂ phase formation. The maximum size of single crystals of 200 x 200 x 50 μ m³ for a flux composition Mg₅₀Cu₄₀B₁₀ and $T_0 = 1050$ °C was achieved. MgO particles contained in the melt seem to be one of the limiting factors for crystallite size since they may act as seeds for MgB₂ crystallization.

Two different crystallization modes of MgB₂, a peritectic reaction with MgB₄ and primary growth of MgB₂ particles from the melt, have been identified depending on initial melt temperature and flux composition. From the analysis of Mg-Cu phases around MgB₂ particles and the starting melt composition a rough estimate of MgB₂ phase formation temperatures (between 780°C and 1000°C) can be inferred.

So far the superconducting properties of MgB₂ crystals can only be deduced from ACsusceptibility measurements of Mg-Cu-B flux bars. The highest $T_c = 39.2$ K and a narrow transition width have been measured in the specimen containing peritectically formed MgB₂ particles assumed to be close to stoichiometric composition. The lower the liquidus temperature of primarily formed plate-like MgB₂ single crystals the larger is the deviation from stoichiometry resulting in lower T_c and extended transition widths. This behaviour suggests a finite homogeneity range of the MgB₂ compound. Samples which display a liquid immiscibility typically exhibit two superconducting transitions. A sizeable effect of Cu solubility on superconducting properties of MgB_2 can be ruled out. Measurements on isolated MgB_2 single crystals prepared from the Mg-Cu-B flux are under way.
