By introducing a chiralterm into the H am iltonian of the 3-state Pottsm odelon a triangular lattice additional sym m etries are achieved between the clockw ise and anticlockw ise antiferrom agnetic states and the ferrom agnetic state. This model is investigated using M onte C arb m ethods. W e investigate the fullphase diagram and nd evidence for a line of tricritical points separating the ferrom agnetic and antiferrom agnetic phases.

PACS num bers: 75.40.Cx, 75.40 M g

I. IN TRODUCTION

The 3-state nearest neighbour ferrom agnetic Potts m odel¹ on the triangular lattice has a second order phase transition at a nite temperature which can be determined from duality and a star-triangle relation, together with the assumption of a single critical point². The critical exponents are known exactly to be $=\frac{1}{3}$; $=\frac{1}{9}$; $=\frac{13}{9}$ and $=\frac{5}{6}$. However, the anti-ferrom agnetic m odel displays a completely di erent behaviour. It is believed to have a weak rst order transition to a six-fold degenerate ground state^{3,4,5}. In this paper we discuss an extension of the 3-state Pottsm odel^{6,7} to include a chiral term which clearly exposes the rst order nature of this latter transition.

II. THE MODEL

The 3-state Potts model is usually de ned as

$$H = J_{i j}$$
(1)

where the sum is over nearest neighbours and the variables $_{\rm i}$ can have three values A;B;C at each site. For the triangular lattice, it is convenient to divide the lattice into three equivalent interpenetrating sublattices corresponding to the three sites on each triangle. The H am iltonian can then be written as a sum over all triangles

if nearest neighbour bonds are shared between neighbouring triangles:

$$H = H$$

$$H = \frac{J}{2}(_{1 2} + _{2 3} + _{3 1}) \qquad (2)$$

where $_1$; $_2$ and $_3$ correspond to the three sublattices on each triangle.

We now extend this model by adding two additional three-spin terms to each triangle

$$H = + \left(\begin{array}{c} J \\ 2 \end{array} \right) \left(\begin{array}{c} 1 \end{array} \right) \left(\begin{array}{c} 1 \\ 2 \end{array} \right) \left(\begin{array}{c} 1 \end{array} \right) \left(\begin{array}$$

where $_{1 \ 2 \ 3}$ is the Levi-C ivita symbol. The term involving is a chiral term which distinguishes between cyclic and anti-cyclic permutations of the three states on a triangle. The terms involving are equivalent to adding the term $_{1 \ 2 \ 3}^2$ to each triangle. Each triangle has 27 states corresponding to four di erent energies as indicated in Table I.

This extended Potts model was not introduced and studied using real space renorm alization group methods by Young and Lavis⁶. Their results agreed with previous work by Schick and Gri ths⁸ on the conventional3-state Potts model which predicted a second order phase transition for the antiferrom agnet on this lattice. However, more recent M onte Carlo^{3,5} results predict a weak not referred a second set order transition as well as a tricritical point located in the ferrom agnetic region^{4,9}. A related self-dual model which only has the conventional three spin term on the upward triangles also exhibits a tricritical point¹⁰.

In the the present work, we consider the extended P otts space which is described by the three independent coupling parameters J; and . The relationship of our parameters J; and to the parameters K and M de ned by Schick and G ri ths⁸ and the additional parameter P de ned by Young and Laviś is

$$K = (J 2) = T$$

$$M = (3J 2) = T$$

$$P = 2 = T$$
(4)

D egeneracy Con guration Η 1 2 3 3J=2 1 AAA 3 e1 = 2 AAB 18 J=2 $e_2 =$ 3 ABC 3 e3 = ACB 3 $e_4 = +$ 4

where T is the tem perature.

III. SYMMETRIES

The model has a symmetry under the following transformations: If we label the three states as $A_{;B}$; C and the three sublattices as 1;2;3 as in Table I, then the transformation which leaves the states on sublattice 1 unchanged but performs a cyclic permutation of the states on sublattice 2 and an anti-cyclic permutation of the states on sublattice 3 m aps the congurations on each triangle as follows:

$$e_1 ! e_3; e_2 ! e_2; e_3 ! e_4; e_4 ! e_1$$
 (5)

and the partition function is invariant under all permutations of the parameters e_1 ; e_3 and e_4 .

A convenient set of param eters to label special points and lines in param eter space are 7

$$a = \frac{e_3 e_1}{e_2 e_1}$$

$$b = \frac{e_4 e_1}{e_2 e_1}$$
(6)

The parameters J; and are related to a and b as

$$\frac{1}{J} = \frac{b}{2}$$
$$\frac{1}{J} = \frac{3}{2}$$
(7)

Figure 1 shows the possible ground states and the location of models corresponding to special values of (a;b). Under the sym m etries described above, all cases can be m apped into the upper triangular region.

The point F(3=2;3=2) is the usual 3-state nearest neighbour ferrom agnetic Potts model which corresponds to = 0; = 0 and AF is the corresponding antiferrom agnetic model which maps under the symm etries of the extended model to the point (0;3). The point

(1;1) corresponds to J = 2; = 0 and is equivalent to a 3-state Pottsm odelw ith only the usual three spin term non-zero and coupling J. The point (1;2) is an in age of the model with only the chiral term non-zero. All ordered phases meet at the point G (0;0).

FIG.1: The possible ground states and the location ofm odels corresponding to special values of (a;b). Under the symmetries described above, all cases can be mapped into the upper triangular region.

IV. RESULTS

The extended Potts model studied here can also be represented in term s of a spin-1 Ising model⁶. Identifying the 3 states A; B; C as the spin states $S_1 = 1;0$ at each site i, we choose the following order parameter

$$\mathbf{m} = \mathbf{j}\mathbf{m}_1 \mathbf{j} + \mathbf{j}\mathbf{m}_2 \mathbf{j} + \mathbf{j}\mathbf{m}_3 \mathbf{j} \tag{8}$$

where m ; = 1;2;3 are the sublattice spin m agnetizations. At high temperatures, all three states have equal weights and the sublattice m agnetizations are zero apart from nite size e ects. At low temperatures, the sublattices become ordered into one of the three possible states. In the ferrom agnetic phase, the sublattices have the sam e state. However in the anitferrom agnetic regions, there can be either a cyclic or anti-cyclic arrangement. We allow for the permutation symmetry of each of these phases by summing mover the permutations. In this way m has the value unity in each of the ordered phases at zero tem – perature. We also calculate the susceptibility and the B inder cumulant U m associated with uctuations in this order parameter.

We have used a standard M etropolis M onte C arlo algorithm to study lattices with N = L^2 sites for values of L ranging from 18 to 96 along the line = 0 joining (3/2,3/2) to (0,3), followed by the line + = 3J=2from (0,3) to (0,0) and nally back along the line = 0 from (0,0) to (3/2,3/2). We present our results for several points along these lines:

Point (1,2)

This point is equivalent under the permutation symmetry to the case where only the parameter is non-zero. The system is expected to exhibit a second order phase transition¹¹ belonging to the same universality class as

TABLE I:Con gurations

FIG.2: Binder cum ulant as a function of T=J for sizes L = 18;24;30;36;42;48 in the case of a = 1;b = 2. The curves cross at $T_c=J = 1.5623$ indicating a continuous transition.

the ferrom agnetic 3-state P otts m odel. O ur M onte C arlo results are consistent with this behaviour. We have calculated the order parameter (m), the susceptibility () and the B inder cum ulant (U m) for lattice sizes ranging from L = 12 to L = 48 where N = L² is the num - ber of sites. Figure 2 shows the B inder cum ulant U m from which the crossing point of the curves for dierent L yields an estimate of the critical temperature. Finite size scaling is then used to collapse the data for both the order parameter and the susceptibility (gure 3) in order to determ ine the critical exponents; and . We nd = 0:11 0:01; = 1:44 0:01 and = 0:82 0:06 which are consistent with this model belonging to the same universality class as the ferrom agnetic 3-state P otts m odel.

PointAF (0,3)

This point is equivalent under the permutation symmetry to the antiferrom agnetic 3-state Potts model and is believed to exhibit a storder them alphase transition. O ur M onte C arb results agree with those of A lder et. al^5 . Figure 4a shows a histogram for the energy per site, e = E = N, at T_c in the case of an 84–84 lattice and gure 4b shows how the energies of the two peaks depend on lattice size. The results indicate a nite jump in the energy in the limit of an in nite lattice. The temperature and energy scales at the point (0;3) are twice as large as at the equivalent AF point in the low er part of gure 1.

We have also studied this latter point directly with = 0 and J < 0. A histogram of the chirality order parameter $_{1/2/3}$ for an 18 18 lattice clearly indicates the rst order nature of the transition. Figure 5 shows the histogram at a few temperatures near T_c which, as mentioned above, has one half the value of the equivalent point at (0,3). At temperatures above T_c, there is a single peak in the distribution at " = 0 but, as the temperature is low ered, two additional side peaks appear

FIG.3: Finite size scaling plots for the order parameter and susceptibility for di erent lattice sizes L and reduced tem – peratures $t = \frac{T T_c}{T_c}$ in the case a = 1; b = 2. a) The order parameter m near T_c yields the values = 0:11 0:01 and = 0:82 0:06. b) The susceptibility yields the values = 1:44 0:01 and = 0:82 0:06.

at nite non-zero values of ". At T_c all three peaks have equal weight and below T_c the two side peaks dom inate. This behaviour clearly indicates that the phase transition is rst order. A continuous transition would correspond to the central peak splitting into two peaks which move continuously away from zero.

Point (0,1)

This point lies on the storder surface separating the AAA and ABC ground states. We have calculated histograms for both the energy and the order parameter m for various lattice sizes L at the corresponding T_c . Both distributions show a double peaked structure as T_c is approached. Figure 6 shows how the peak energies and m agnetizations vary with L. Again we nd a storder them all phase transition which is stronger than at the AF point.

FIG. 4: a) Histogram for the energy per site, e = E = N, at $T_c=J = 1.256$ in the case a = 0;b = 3 which is equivalent to the 3-state Potts antiferrom agnet. b) Dependence of the histogram peak energies on lattice size. Extrapolation to the large L limit indicates a nite jump in the energy at T_c .

FIG .5: H istogram for the chirality " at various tem peratures near $T_{\rm c}$ at the AF point with J < 0.

FIG. 6: Dependence of the histogram peak locations on lattice size for the case a = 0; b = 1. a) Dependence of the histogram peak energies on lattice size. b) Dependence of the histogram peak magnetizations on lattice size. Extrapolation to the large L limit indicates a nite jump in the both the energy and the order parameter at T_c .

Point G (0,0)

This point corresponds to a meeting of the three st orderplanes separating the AAA, ABC and ACB ground states. Figure 7 show a magnetization histogram for a 48 48 lattice at T_c . The jump in the magnetization is larger than at the point (0,1). We have also studied the behaviour at a large value of b = 10 along the line a = 0and again and a st order transition which is weaker than at the AF point.

W e have also investigated the possibility of a tricritical point along the line a = b using the histogram s. Figure 8 shows the energy discontinuity as a function of a. The results were obtained by calculating histogram s for various lattice sizes and extrapolating to the large L limit. The energy jump decreases as we move upward from the point G (0;0). A tricritical point exists very close to a = b = 0.35 which is in between the values reported by

FIG. 7: M agnetization histogram at the point G (0,0) for a 48 48 lattice at T_c. The peaks of the distribution are more widely separated than at the point (0,1).

FIG. 8: The energy jump as a function of a along the line a = b. A tricritical point exists near a = b = 0.35.

the series⁹ and previous M onte C arlo results⁴.

Figure 9 show s the phase diagram along the closed path (3=2;3=2) ! (0;3) ! (0;0) ! (3=2;3=2) obtained using our M onte C arlo m ethod. A long the rst section of the path, the second order transition changes to a rst order transition at the point labelled T which is quite close to the AF point. A swe then m ove tow ands the point G (0;0) along the line a = 0, the transition remains rst order with the transition temperature decreasing and the size of the energy and order parameter discontinuities increasing. Finally, along the section of the path m oving back to the point F the rst order transition again changes to a second order transition near the point a = b = :35. The points labelled by T are tricritical points.

Figure 10 shows a schem atic phase diagram in the a b plane where shaded areas correspond to rst order transitions. The shaded region narrows appreciably near the

FIG.9: The phase diagram along the closed path = 0!+ = 3J=2! = 0 obtained using a heat-bath M onte C arlo m ethod. Solid lines indicate second order transitions and dashed lines indicate rst order transitions. Tricritical points are indicated by the letter T.

FIG.10: A schematic picture of the phase diagram in the extended Potts space. The shaded area is a region of rst order therm al phase transitions. The region narrows substantially near the AF point indicating a weak rst order transition.

AF point which is consistent with a weak rst order transition.

V. SUMMARY

We have studied an extended 3-state Potts model on the triangular lattice using M onte C arlo m ethods. The extended m odel includes a chiral term which distinguishes between cyclic and anti-cyclic con gurations on each triangle and clearly exposes the rst order nature of the nearest-neighbour anti-ferrom agnet.

In the regions corresponding to continuous transitions,

the model belongs to the 3-state ferrom agnetic Potts model universality class. We have not been able to locate the tricritical line with su cient precision to determ ine the tricritical exponents.
