We propose, theoretically, a new type of quantum field effect transistor that operates purely on the flow of spin current in the absence of charge current. This spin field effect transistor (SFET) is constructed without any magnetic material, but with the help of spin injection mechanism provided by a rotating external magnetic field of uniform strength. The SFET generates a constant instantaneous spin current that is sensitively controllable by a gate voltage as well as by the frequency and strength of the rotating field. The characteristics of a Carbon nanotube based SFET is provided as an example.

85.35.-p 72.25.Mk 74.40.-c 85.35.Kt

Silicon based field effect transistors (FET) have played a pivotal role in the technology that drives the microelectronics revolution. It has however been projected that Si technology is rapidly approaching its limit of miniaturization¹, and various new and exciting ideas of nano-electronics have been proposed and pursued. One of the most important possibilities of nano-electronics is the hope of using spin in addition to charge, for nonlinear electronic device applications². So far, progress has been achieved in certain areas of spintronics such as device applications based on the giant magnetoresistive effect³, the understanding of material properties of magnetic semiconductors⁴, the improvements of spin injection across a magnetic/nonmagnetic interface⁵, and optical manipulation of spin degrees of freedom in nanostructures⁶. On the other hand, despite the fact that it is already more than ten years since the proposal⁷ of FET operation on spin-polarized charge current, the spin-FET (SFET) has been an elusive system up to now. The overwhelming majority of actual spintronics devices and proposals up to now are hybrid systems which involve both magnetic and non-magnetic materials². Due to differences in chemical bonding and structural property of them, these hybrid materials have proven to be rather challenging to use. This, together with several other physical factors related to spin transport, has limited the rapid development of practical nonlinear spintronic devices such as the SFET.

In this paper, we take a different direction by theoretically examining the possibility of SFET operation without involving magnetic materials and we exploit such a novel SFET which operates purely on spin current. This SFET turns out to be realizable as we predict, in coherent nanostructures (such as a quantum dot, a quantum well, or a Carbon nanotube), in the presence of a rotating external magnetic field of uniform strength. Importantly,

the rotating field induces a time-independent (i.e. a DC) spin current, and at the same time it generates no charge current (see below). The magnitude of the spin current is critically tunable by a gate voltage which shifts the electronic levels of the non-magnetic nanostructure so that SFET operation is achieved. The physical principle of our SFET is due to spin injection mechanism provided by the field, but is ultimately connected to the quantum physics of Berry's phase⁸. Because no magnetic material is involved in our SFET, any problem that relates to spin injection across a magnetic-nonmagnetic interface is bypassed. Moreover, because there is no charge current involved, our SFET will be less affected by problems of heat dissipation. Since many non-magnetic nanostructures, such as a Carbon nanotube, have long spin coherent lengths⁹, our proposed quantum SFET should be experimentally realizable. To provide a concrete numerical example, we predict the transport characteristics of an all-nanotube based SFET.

Consider a three-probe non-magnetic device shown in the inset of Fig.1 which consists of a scattering region Ohmic-contacted by two probes while the third probe is a metallic gate capacitively coupled to the scattering region. Here we used a section of an arm chair carbon nanotube as the scattering region, but in general it can be a quantum dot, a quantum well, or other mesoscopic conductors. The system can be 2d or 3d. In this work, we consider the following Hamiltonian of this device ($\hbar = 1$):

$$H = \sum_{k; \sigma} C_k^\dagger C_k + \sum_{k; \sigma} [A_k C_k^\dagger + B_0 \cos(kd)] d^\dagger d + H^0(t) + \sum_{k; \sigma} [\Gamma_k C_k^\dagger d + \text{c.c.}] \quad (1)$$

where $H^0(t)$ is the off-diagonal part (in spin space) of the Hamiltonian,

$$H^0(t) = [\exp(-i\Omega t) d_\uparrow^\dagger d_\downarrow + \exp(i\Omega t) d_\downarrow^\dagger d_\uparrow]; \quad (2)$$

with $\Omega = B_0 \sin \theta$. In the Hamiltonian (1), the first term stands for the Hamiltonian of noninteracting electrons in the leads with C_k^\dagger the creation operators in lead. Note that we have set the same chemical potential for both leads because, as we will see below, a rotating magnetic field will "pump" out a DC spin current without needing a bias voltage. Quantum parametric pumping of charge current has been well analyzed before¹⁰, and here we demonstrate that pumping of a spin current will lead to SFET operation. The second term and $H^0(t)$ correspond to the Hamiltonian of the

scattering region which is subjected to a time-dependent (rotating) magnetic field with uniform strength, $B(t) = B_0 [\sin \cos \omega t + \sin \sin \omega t + \cos k]$ where B_0 is the constant field strength. The scattering region is characterized by an energy level $\epsilon_0 = qV_g$ which can be controlled by the gate voltage V_g (see inset of Fig.1). We have only included the coupling between magnetic field and the spin degrees of freedom. It is however not difficult to confirm that the orbital degrees of freedom do not contribute to the current in the presence of time varying magnetic field. This is because in the presence of magnetic field, the hopping matrix element between sites i and j , t_{ij} , in the tight binding description, will be modified by a phase factor $\exp[i \phi_{ij}]$ with $\phi_{ij} = A \cdot (r_i - r_j)$. But ϕ_{ij} due to our rotating magnetic field in the $x-y$ plane is simply zero, therefore the orbital parameter t_{ij} is not affected by the rotating field. The third term in Eq.(1) denotes coupling between the scattering region and lead with coupling matrix elements T_k . In the following we solve the transport properties (charge and spin currents) of the model in both adiabatic and non-adiabatic regimes using the standard Keldysh nonequilibrium Green's function (NEGF) technique^{11,12}.

A diabolic regime. A diabolic regime is when the external parameter varies very slowly, i.e. in the $\hbar \omega \ll 0$ limit. In this regime the charge with spin transported from lead in time interval dt is given by¹³

$$dQ(t) = q \frac{dE}{2} (\text{Tr} f) [G^r(t) - G^a(t)] dt \quad (3)$$

where $G^r(t)$ is the retarded Green's function and $G^a(t) = [G^r(t)]^\dagger$ is the advanced Green's function. In the adiabatic limit,

$$G^r(t) = \frac{1}{z} \frac{E_1 - E_2}{E_1 - E_2} e^{i\omega t} \quad ; \quad (4)$$

where $z = (E_1 - E_2)^2$, $E_{1,2} = B_0 \cos \phi_{1,2}$ and ϕ is the linewidth function. We will apply the wideband limit so that ϕ is independent of energy. In Eq.(3), quantity dH/dt where H^0 is the 2×2 matrix in spin space given by Eq.(2),

$$H^0 = \begin{pmatrix} 0 & e^{i\omega t} \\ e^{-i\omega t} & 0 \end{pmatrix} \quad ; \quad (5)$$

Using Eqs.(3,5,4), the instantaneous electric current is found to be (Fermi energy and temperature are set to zero):

$$\frac{dQ}{dt} = \frac{dQ}{dt} = \frac{q \omega}{2} \frac{1}{\omega} \quad ; \quad (6)$$

Several observations are in order for this result. First, spin ip mechanism (due to Eq.(5)) in the scattering region is provided by the rotating magnetic field with processes in which photons are absorbed and re-emitted. As a result, the instantaneous current is actually time-independent as Eq.(6). Second, the total instantaneous

charge current $dQ/dt = dQ/dt = 0$ identically, i.e. a rotating magnetic field does not pump a charge current. Third, There is a nonzero spin current $I_s = ds/dt = (1/q)dQ/dt$. From Eq.(6), the spin current depends on field strength B_0 , frequency ω of the rotating field, and more importantly on the energy level positions $\epsilon_{1,2}$ which is modulated by the gate voltage. It is this modulation which provides the operation principle of our SFET.

The maximum spin current in the adiabatic regime is obtained by setting $\omega = 2$ and $\epsilon_0 = 0$, we have

$$I_s = \frac{1}{4} \frac{1}{1 + 1} = \frac{1}{8} \quad ; \quad (7)$$

This lineshape involving fourth power of the relevant quantities, is ideal for SFET operation: I_s is very sensitive to the energy level position which is controlled by the gate voltage. For instance, at resonance $\epsilon_0 = 0$ the spin current reaches its maximum value $I_s = 1/8$. However, when ϵ_0 is varied by V_g to 10 ($\epsilon_0 = 2$), the spin current is reduced by a factor of 10^4 . Since $I_s = s \cdot \omega$ with $\omega = 2$ being the period of rotating magnetic field, we therefore conclude that at resonance, our device pumps out exactly one spin through the left or the right lead in one rotation. This quantization of pumped spin is substantially easier to realize than that of charge^{15,16} in a charge pump. It is easy to show that for a multi-probe system such as ours, the total spin pumped out of the device is two spin quanta. But if there is only one lead connected to the scattering region, the spin current is given by Eq.(7) multiplied by a factor of two: in this case our device can be viewed as a nonmagnetic version of spin battery^{14,17}.

Why our device can pump out a DC spin current without a bias? As pointed out by Avron et al⁹, in a quantum parametric charge pump, the pumped charge per cycle is related to the Berry's phase⁸. This physical picture can be easily generalized to the case of spin current discussed in this work. In fact, using the

spinor $j = \begin{pmatrix} s_{11} \\ s_{21} \end{pmatrix}$ with s_{ij} the scattering matrix,

the pumped charge can be obtained¹⁹ from the definition of Berry's phase $\phi = \int_0^T \langle \psi(t) | d\psi(t) \rangle dt$ where $\langle \psi(t) | = \langle R(t) | j - \langle R(t) |$, $R(t)$ label the slowly varying system parameters, and T is the period of variation. Note that in the case of charge pumping, $\langle \psi(t) |$ corresponds to the instantaneous pumped charge. Setting $T_k = 0$ in Eq.(1), it is easy to verify²⁰ that $\phi(t)$ (instantaneous phase) is independent of time.

Non-adiabatic regime. The electric and spin current beyond the adiabatic approximation can be calculated exactly using NEGF. It is convenient to define the particle current operator in spin space,

$$\hat{J}_s = \frac{1}{i} \sum_k \frac{d[C_k^\dagger C_k]}{dt} = \sum_k [T_k C_k^\dagger d - T_k^\dagger d^\dagger C_k] \quad ; \quad (8)$$

Then the electric current operator is $\hat{I}_{\text{el}} = q \hat{J}$, and the spin current operator is $I_s = \frac{1}{2} \hat{J} \cdot \hat{s}$ where $s = \pm 2$. From (8) we compute particle current

$$J_X(t) = \frac{1}{L} \sum_k [\Gamma_k G_{d,jk}^<(t;t) - T_k G_{k,jd}^<(t;t)] \quad (9)$$

where the NEGFs are defined as $G_{d,jk}^<(t;t^0) = i \langle C_k^\dagger(t^0) d(t) \rangle$, $G_{k,jd}^<(t;t^0) = i \langle d^\dagger(t^0) C_k(t) \rangle$. They are calculated by the Keldysh equation $G^< = G^r < G^a$ in standard fashion^{11,12}. Therefore, the transport problem is reduced to the calculation of the retarded Green's function $G^r(t;t^0)$.

In general, a perturbation theory is needed to solve a time-dependent problem. Fortunately, for the time-dependent Hamiltonian considered here, $G^r(t;t^0)$ can be solved exactly as follows. It is simple to obtain the retarded Green's function for the diagonal part (in spin space) of the Hamiltonian (1),

$$G^{0r}(t-t^0) = i(t-t^0) \begin{matrix} e^{i\omega_1(t-t^0)} & 0 \\ 0 & e^{i\omega_2(t-t^0)} \end{matrix}$$

The full Green's function of Hamiltonian (1) is then calculated by the Dyson equation in spin space,

$$G^r(t;t^0) = G_Z^{0r}(t-t^0) + \int dt_x G^{0r}(t-t_x) H^0(t_x) G^{0r}(t_x-t^0) +$$

where H^0 is given by Eq.(5). After applying the double-time Fourier transform, the Dyson equation can be summed up exactly to obtain the exact Green's function of the model (1):

$$G^r(E;E^0) = \frac{2(E-E^0)G^{0r}(E)}{1 - 2g(E)}$$

$$G^r(E;E^0) = 2(E + \Delta - E^0) \frac{g(E)}{1 - 2g(E)}$$

where $g(E) = G^{0r}(E)G^{0r}(E + \Delta)$, $\Delta = \frac{1}{2} \hbar \omega$, and $\omega = \omega_{\text{L}} = 1$.

Using these relations, it is straightforward to obtain particle current from Eq.(9)

$$J_{L,\text{el}} = J_{L,\text{el}} = \frac{2}{L} \frac{dE}{2\pi} \int_{-\infty}^{\infty} [f(E) - f(E + \Delta)] \frac{2g^{0r}(E)g^{0r}(E + \Delta)}{1 - 2g^{0r}(E)g^{0r}(E + \Delta)} dE \quad (10)$$

and $J_{L,\text{el}} = 0$, where $E = E + \Delta$. This result²¹ allows us to conclude that the charge current is still identically zero while the spin current is given by

$$I_{sL} = J_{L,\text{el}} k \quad (11)$$

which is independent of time. These qualitative features are the same as those of the adiabatic limit discussed above. However, the non-adiabatic result (10) involves processes with energies $E \pm \Delta$, as shown by the arguments of the Green's functions. This indicates that in the general non-adiabatic situation, many single photon processes are participating the operation of the SFET device.

Nanotube SFET. We now apply the general principle of our SFET to a (5,5) arm chair single wall Carbon nanotube (CNT) with 200 unit cells which is contacted by two electrodes and gated by a third probe, as shown in the inset of Fig.1. For simplicity, the CNT is modeled with the nearest-neighbor π -orbital tight-binding model with bond potential $V_{pp} = 2.75$ eV for the carbon atoms. This model is known to give a reasonable, qualitative description of the electronic and transport properties of carbon nanotubes²². Using Eq.(10) the spin current flowing out of the CNT SFET in the adiabatic regime can be written as $I_s = \frac{1}{4} T$ where

$$T = \frac{2}{(\omega^2 + \omega_1^2 + 4\omega_2^2)^2 + \omega^2} \quad (12)$$

Clearly, if $\omega = 2$, there is only one peak with $T = 1$. If $\omega > 2$, there are two peaks with $T = 1$. We note that Eq.(12) is the same as that of the Andreev reflection coefficient in the presence of superconducting lead (NS system). This can be understood as follows. For simplicity we assume a single probe connected to the scattering region. Because of the rotating magnetic field, an incoming spin-up electron (the electron in NS case) is flipped down and pumped out as a spin-down electron (the hole in NS case) which is analogous to the Andreev reflection. Fig.1 shows the spin current I_s versus the gate voltage V_g for different ω with $\Delta = 0.01$ (corresponds to 86 MHz in our units) and $\omega = 88^\circ$. Here $\omega = 0.1$ corresponds to $B = 0.06$ Tesla. Very similar results are obtained for other ω . The resonant spin current transport is clearly seen by which I_s increases from practically zero to large values under the control of V_g . Fig.2 displays the spin current versus frequency using the nonadiabatic result Eq.(10), with $\omega = 50^\circ$, $\Delta = 0.5$ and $V_g = 0.0$. The nonlinearity sets in at about $\omega = 0.7$. Finally the inset of Fig.2 depicts spin current as a function of ω with $\Delta = 0.01$, $\omega = 0.5$, and $V_g = 0.0$. The spin current is rather substantial for a wide range of angles.

In summary, we have demonstrated that a rotating magnetic field of uniform strength induces a spin current without a charge current, in coherent quantum conductors without needing any magnetic material. The spin current is critically tunable through the control of a resonance level in the system by an external gate voltage, thereby generating a field effect transistor operation. The physics behind this phenomenon is the spin-flip mechanism by the external field, but is ultimately related to the quantum physics of the Berry's phase⁸. Because spin current can be detected using an idea proposed by Hirsch²³,

the rotating frequency of the field needs not to be large, and the device structure is quite typical, we believe the SFET proposed here should be experimentally realizable.

- ¹⁷ The spin battery concept of Ref.(14) involves a ferromagnetic|semiconductor interface and a rotating magnetic moment of the ferromagnet. The system studied here can behave as a spin battery, although there is no ferromagnetic material, if we contact the scattering region by only one lead. From a device operation point of view, the scattering region has its own electronic structure (the energy levels) which induces resonance control of the spin current compared with a ferromagnetic|semiconductor interface. Finally, our device is controlled by an external field, rather than by internal magnetic moment. Therefore it does not suffer from the damping effect of rotating magnetic moment that consumes considerable amount of energy¹⁸.
