(April 14, 2024)

The current-voltage (IV) characteristics for perpendicular transport through two sequentially coupled wires of finite length is calculated analytically. The transport within a Coulomb blockade step is assisted by plasmon resonances that appear as steps in the IV characteristics with positions and heights depending on inter- and intrawire interactions. In particular, due to the interwire interactions, the peak positions shift to lower voltages in comparison to the noninteracting wires which reflects the facilitation of current by interactions. The interwire interactions are also found to enhance the thermally activated current.

Recent technological progress in creation of clean one-dimensional wires, either as carbon nanotubes<sup>1</sup> or as a part of semiconductor structures<sup>2</sup> has attracted much attention to the study of transport through quasi-one-dimensional systems, both experimentally and theoretically.<sup>1-7</sup> Transport through clean quasi-one-dimensional systems probes the main consequences of the Luttinger liquid (LL) theory<sup>8</sup>, the spin-charge separation and the charge fractionalization. Experimentally, quasi-1d systems have a finite length, or they are effectively divided into finite size fragments by impurities<sup>7</sup>. If the length is not very large, the quasi-1d systems actually represent one-dimensional quantum dots, with finite charging energy and discrete spectrum.<sup>1,9</sup> Therefore, the theoretical study of finite-size effects on transport through wires of finite length  $L$  that form the LL in the limit  $L \rightarrow \infty$  is of much importance for the interpretation of experiments<sup>7</sup>.

In this Letter, we address those features of a LL that can be seen in experiments on perpendicular transport through two coupled quantum wires of finite length  $L$ , analyzing the current-voltage (IV) characteristics of the circuit consisting of the left reservoir, two quantum wires, and the right reservoir, coupled in sequence (see the inset in Fig. 1). The reservoirs are assumed to be noninteracting. There is a magnetic field applied perpendicular to the plane of the wires. Such system can be realized in form of two carbon nanotubes. A similar geometry has been employed in experiments on semiconductor structures<sup>2</sup> with the difference that only one of the wires is of finite length there. Since the discreteness of the spectrum is explicitly taken into account, the results presented here may find analogies in experiments on double quantum dots<sup>10</sup>. We do not consider spin effects, the Luttinger liquids are assumed to be spinless. We derive an analytical expression for the current-voltage characteristics in lowest order in tunneling to the reservoirs, concentrating on the region within a single Coulomb blockade step.

We found that the interwire interactions facilitate transport at finite bias voltages, as well as thermally activated transport. Our results on IV characteristics are summarized in Fig. 1. The discreteness of the spectrum of a finite-length wire transforms the power-law singularities, typical for the LL, into a series of discrete steps with envelope described by the power-law function of the infinite system<sup>13</sup>. Each step in the IV characteristics corresponds to a plasmon resonance between the LL wires. The positions of the steps of the IV curve reflect the quantization of the charge mode of the LL, in particular, the energies of two independent bosonic modes, propagating on the length  $L$  with velocities  $u_1$  and  $u_2$ .<sup>6</sup> One of the velocities ( $u_2$  in our case) always renormalizes down by interwire interactions, which results in the lowering of plasmon excitation energies, and hence the facilitation of transport through excited states as compared to the noninteracting wires. The height of each step reflects the strength of the corresponding plasmon resonance, and is also controlled by LL interaction constants. Therefore, IV characteristics should clearly demonstrate the effect of LL interactions. The outlined features are rather insensitive to the geometry of the reservoirs. They can be seen in the case of two- and three-dimensional reservoirs contacted along a whole wire, as well as for a circuit with point-like coupling between the reservoirs and the wires, such as that realized in STM experiments<sup>1,3</sup>. In contrast, due to strong restrictions imposed by momentum conservation by tunneling, the interaction effects can hardly be seen in the case of one-dimensional reservoirs parallel to the wires.

Our starting point is the Hamiltonian of two interacting Luttinger liquids of finite length, with different Fermi-velocities  $v_1$  and  $v_2$  and with a single-particle (1P) tunneling of amplitude  $t$  between the LL's. The length of the wires  $L$  is assumed to be large, so that the wave number  $k$  is conserved in the tunneling

process. In the presence of a magnetic field  $B$  perpendicular to the plane, the states of the wire 1 and the left reservoir acquire an additional phase factor  $e^{ibx}$  ( $b = eB/\hbar$ ,  $x$  denotes a coordinate along the wire) with respect to the states of the wire 2 and the right reservoir<sup>6</sup>. The application of the LL approach to wires of finite length is limited by the condition that the screening length for the Coulomb interaction in the wire is much less than the length of the wire  $L$ . This condition is fulfilled, for example, in recent experiments on semiconductors<sup>2,4</sup>.

We take into account the electrostatic charging energy phenomenologically, shifting the groundstate energy by the capacitive energy  $E(N_1; N_2)$ , where  $N_1; N_2$  denote the total number of electrons in the first and the second wire respectively. The calculation of  $E(N_1; N_2)$  has been performed previously<sup>5,11</sup>. Furthermore, it is assumed that the application of voltage between the wires shifts the energy of the one-particle states of the two wires by the amount  $eV$  relative to each other (band-shifting case<sup>5</sup>).

Since transport between the LL's is determined by plasmon resonances, and in resonance the interwire tunneling has to be treated exactly, we first diagonalize the 1P spectrum. The spectrum of the diagonalized 1P Hamiltonian consists of two branches with dispersions  $\epsilon(k) = eV + (v_1 + v_2)k \pm \sqrt{(eV + (v_1 - v_2)k)^2 + 4t^2}/2$ . In general, the resulting spectrum is not linear anymore for  $v_1 \neq v_2$ . However, as long as  $|eV + (v_1 - v_2)k| \gg eV^2 + 4t^2$  one can expand the square root, and retaining only the first term of expansion consider the spectrum as approximately linear. Further we work in that approximation. Upon inclusion of two-particle interactions, the two branches  $\epsilon(k)$  form two new interacting Luttinger liquids.

After the diagonalization of the 1P part of the two-wire Hamiltonian, the physical picture changes from the sequential circuit, the left reservoir { two coupled wires } the right reservoir, to the circuit, where there are two LL's coupled in parallel to the left and right reservoirs with no direct tunneling between the Luttinger liquids.

Note that two particle hopping terms between the new LL's in the particle-particle (pp) and particle-hole (ph) channels<sup>12</sup> are generated by the diagonalization of 1P Hamiltonian. These terms will be omitted in further consideration. Their amplitudes are small at small tunneling  $t$ , though they play a crucial role close to the instability in the ph or pp channel (see below).

After the 1P diagonalization, the Hamiltonian of interacting LL's without the one-particle tunneling is of the form  $H = \sum_{i=1,2} H_i + H_{12}$ ; where  $H_i$  is a standard LL Hamiltonian without backward scattering<sup>16</sup>, and the interwire interaction is of the form  $H_{12} = \sum_{L=2}^{R=L=2} \frac{dx}{2} : [\hat{\rho}_{1L} \hat{\rho}_{2R} + \hat{\rho}_{1L} \hat{\rho}_{2L} + L \hat{\rho}_R] : : 2$  and  $\hat{\rho}_i$  are the interwire interaction constants,  $\hat{\rho}_{R;L}(x)$  denote the chiral electron density operators of the two wires.

In the bosonized form, the Hamiltonian looks like (here  $\tilde{\alpha}_i = (\alpha_i; \beta_i)^T$ ,  $\tilde{\alpha}_i = (\alpha_i; \beta_i)^T$ )

$$H = \frac{1}{4} \sum_{L=2}^Z \frac{dx}{2} : \tilde{\alpha}_x^T \hat{M} \tilde{\alpha}_x + : \tilde{\alpha}_x^T \hat{M} \tilde{\alpha}_x : ; \quad (1)$$

where  $\hat{M} = \begin{pmatrix} v_1 g_1 & v_1 (g_4 + g_2) \\ v_1 (g_4 + g_2) & v_2 g_2 \end{pmatrix}$ ,  $\hat{M} = \begin{pmatrix} v_1 g_1 & v_1 (g_4 + g_2) \\ v_1 (g_4 + g_2) & v_2 g_2 \end{pmatrix}$ ,  $v$  is the charge mode velocity in wire and  $g$  is the LL interaction constant for wire. Diagonalization of the Hamiltonian (1) is achieved by applying a composition of unitary rotations and subsequent rescalings, whereby the rescalings preserve the duality of the fields  $\alpha_i$  and  $\beta_i$ :  $\alpha_i \rightarrow K_i \alpha_i$ ,  $\beta_i \rightarrow K_i \beta_i$ . The same has been achieved by other means in<sup>6,12,14</sup>. The diagonalization renders (1) to the Hamiltonian of two uncoupled LL's with different charge mode velocities,  $u_1$  and  $u_2$ :  $H = \sum_{i=1,2} \frac{u_i}{2} \frac{dx}{2} : (\alpha_x^i)^2 + : (\beta_x^i)^2 : ;$  where the dual fields  $\alpha_i$ ,  $\beta_i$  are related to the original ones by linear transformations  $\tilde{\alpha} = \hat{Q} (\alpha_1; \alpha_2)^T$ ,  $\tilde{\beta} = \hat{Q} (\beta_1; \beta_2)^T$ . In the case of identical wires,  $v_1 = v_2 = v$ ,  $g_1 = g_2 = g$ , the matrices  $\hat{Q}$  are given by  $Q^{11} = \frac{1}{2} \frac{1+g+g_4+g_2}{g+g_4+g_2}$ ,  $Q^{22} = \frac{1}{2} \frac{1-g-4+g_2}{g-4+g_2}$ , and  $Q^{ij} = 1/(2Q^{ij})$ . The behavior of the renormalized velocities  $u_1$  and  $u_2$  versus the interwire coupling strength at different values of intrawire interaction constant is shown in the inset in Fig. 1. Each velocity determines the interlevel spacing for a branch of the plasmon spectrum by the relation  $\epsilon_i = u_i L$ ; ( $i = 1; 2$ ). The velocity  $u_2$  that renormalizes down by interwire interactions corresponds to the mode, where the charges of two wires fluctuate in antiphase (the pseudospin mode in the case of identical wires<sup>6,12,16</sup>). There is a special point in the dependence of the renormalized velocities on interwire interactions, where  $u_1 = u_2$ . For identical wires, this point is given by the relation  $(g_4 + g_2)g = (g_2 - g_4)g$ . The farther away from that point,

the lower is the velocity  $u_2$ . Moreover,  $u_2$  turns to zero when one of the matrices,  $M$  or  $M$  becomes degenerate. The latter happens when interwire and intrawire interactions are comparable. Particularly, in the case of identical wires, and for  $u_2 = 0$ ,  $u_2 = 0$  is reached for  $u_4 = v_F$ . The interwire tunneling in coupled finite LL's is known to result in an instability either in the ph or in the pp channel at strong enough interwire interaction<sup>12</sup>. We expect that one of those two instabilities occurs at the point  $u_2 = 0$ , even though the length of the wires is finite. Indeed, the velocity  $u_2$  changes the effective length of the wire for the corresponding plasmon mode by the obvious relation  $L \rightarrow L + u_2$ , hence the physics of an infinite LL should be recovered for  $u_2 \rightarrow 0$ . Complete analysis of the instability employing the renormalization group treatment is left for future publication.

Now we turn to the implications of the above results for the current-voltage characteristics. We consider here the case, when tunneling between a wire and the next reservoir is much larger than tunneling between the wires. Then the whole voltage drop takes place between the wires. Increasing the bias voltage, the energy difference between the two 1P spectral branches  $\epsilon_+(k)$  and  $\epsilon_-(k)$  increases, which results in the suppression of tunneling matrix elements  $T_{1,r}$  and  $T_{2,l}$  ( $i = 1, 2$  relates to the LL channel,  $r = l$  relates to the reservoir), and hence to the suppression of current. However, for a given chirality ( $\sigma = 1$  for the left,  $\sigma = -1$  for the right chirality), that effect can be compensated by changing the external magnetic field according to  $b = \pm eV/v_F$  (then both LL channels have the electrochemical potential close to the left reservoir) or  $b = \mp eV/v_F$  (then both LL channels have the electrochemical potential close to the right reservoir). In what follows we consider the case  $b = -eV/v_F$ .

The single-particle tunneling current  $I$  under the applied voltage  $V$  is given by the sum of the currents through the two parallel LL channels. In each channel, there are contributions from states with the left and the right chiralities. The calculation of the current is outlined in Ref. [15], whereas we use the bosonization formulas for a finite length wire with free boundary conditions to calculate the fermion correlation function in each channel<sup>16</sup>. Furthermore, we describe the reservoirs in terms of their density of states with energy  $\epsilon_{r,l}(\epsilon)$ . That is appropriate in the case of two- and three-dimensional reservoirs with large bandwidth, where the momentum conservation by tunneling does not impose a restriction on energy. The current-voltage characteristics is obtained as follows,

$$I_{i,r}(\text{eV}) = \frac{16e}{a} \sum_{n,m=0}^{\infty} \frac{b_{i1}^{(n)} b_{i2}^{(m)}}{n! m!} \left( \langle \epsilon_{i,m,n} \rangle_r \langle \epsilon_{i,m,n} \rangle_l \right) \left( \langle \epsilon_{i,m,n} \rangle_r \langle \epsilon_{i,m,n} \rangle_l \right); \quad (2)$$

where  $b_{i1} = (Q^{i1})^2 + (Q^{i1})^2$ ,  $b_{i2} = (Q^{i2})^2 + (Q^{i2})^2$ ,  $\epsilon_{i,m,n} = E(N_i - 1; N_j) - E(N_i; N_j) - (v_F + nu_1 + m u_2)L = eV$ , and  $a$  is a short-range cutoff. Each term in the sum over  $n, m$  describes the contribution from a plasmon resonance between the two wires to the current. The tunneling density of states represents a superposition of two sequences of equidistant peaks with periods  $u_1 = L$  and  $u_2 = L$ . Both the position and the weight of each peak is completely defined by interactions. The structure of the tunneling density of states has much in common with the structure of photoluminescence spectra from highly excited nanorings, described in detail in Ref. [14]. Indeed, in both cases the correlations of two finite size LL's determine the relevant physics with the difference, that it is the four-point correlation function that determines the luminescence spectra.

A set of IV characteristics for different values of interwire interaction  $u_4$  is shown in Fig. 1. The shift of the position of the second step to lower voltages with increasing  $u_4$ , which corresponds to the current through the first excited plasmon state, demonstrates the facilitation of current by interwire interactions. For single wall carbon nanotubes, the charging energy is 3 to 6 times the noninteracting interlevel spacing,<sup>1,3,9</sup> independently of the nanotube length. Therefore, the plasmon resonances with  $m, n = 3 \dots 6$  are expected to be seen experimentally within a single Coulomb blockade step.

For one-dimensional reservoirs, the momentum conservation by tunneling fixes the energy difference between the modes in the reservoir and in the two-wire system. The IV curve yields a sequence of peaks. The positions of the peaks are determined by interference phenomena, which are only partially controlled by interactions. Moreover, even applying an external magnetic field, it is generally impossible to satisfy the momentum conservation and to avoid the dimming of tunneling by the bias voltage simultaneously. We conclude that the interaction effects can hardly be seen if the reservoirs are one-dimensional.

Another effect of interactions is in facilitating plasmon assisted transport at small voltages and finite

temperatures. For small temperatures, we obtain  $I(T) = I_{1r}(T) + I_{21}(T)$ , where

$$I_{i,} = \frac{2 V T_{i,} \int_0^{\frac{v_i}{L T}} (F) \exp \frac{v_i}{L T} :}{1 - e^{-\frac{u_1}{L T}} b_{11}} \frac{1}{1 - e^{-\frac{u_2}{L T}} b_{12}} : \quad (3)$$

The enhancement of the thermally activated current can be seen by comparison of Eq. (3) with the result for the system without the interwire interactions that reads  $I_1 / \exp \frac{v_1}{L T} = 1 - \exp \frac{v_1}{L T}$ . Due to the smaller interlevel distance for plasmon excitations in the interacting system (smaller velocity  $u_2$ ), the thermally activated current is enhanced.

As the singularity  $u_2 \rightarrow 0$  is approached, the distance between the  $m$  and  $m + 1$  step in zero-temperature IV characteristics diminishes, the height of each step grows and formally diverges with  $b_{12}$  at the point  $u_2 = 0$ . The thermally activated current also grows and diverges as a power-law  $(T = u_2)^{b_{12}}$ . To describe the behavior close to the singularity, the ph and pp hopping operators need to be included in the theoretical treatment, which is beyond the scope of the present paper. Beyond the transition, the fluctuations of the fields ( $\phi_2$ ) are frozen and do not contribute to the current. The charge fluctuations actually correspond to a single LL of finite length. The IV characteristics is given by Eq. (2) with  $u_2 = 0$ ;  $b_{12} = 0$ . The thermally activated current is suppressed compared to the noninteracting system, since  $u_1 > v_F$ .

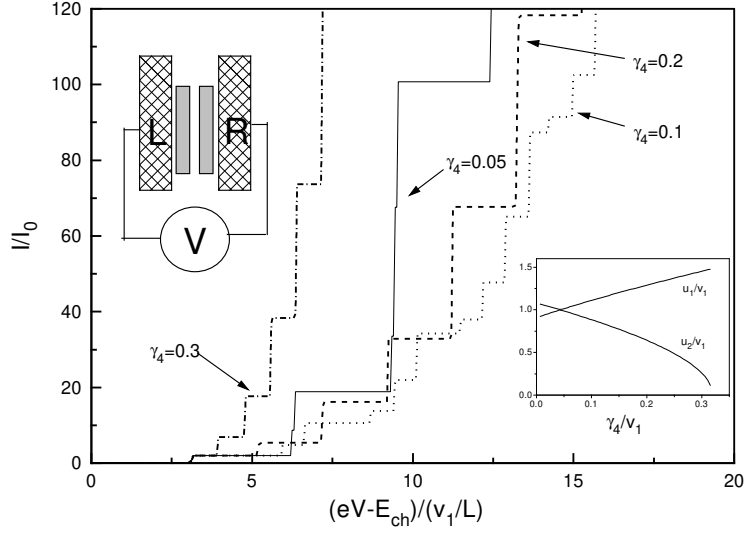

FIG. 1. IV characteristics for different interwire interaction constants  $\gamma_4$ . The position of the second step reflecting the current through the first excited plasmon mode shifts to lower voltages with growing  $\gamma_4$ , which indicates the facilitation of current by interactions. In the shown voltage range, the curves with  $\gamma_4 = 0.2; 0.3$  show equidistant steps, reflecting the contribution of the mode  $u_2$  only, whereas both modes  $u_1$  and  $u_2$  contribute to the curve with  $\gamma_4 = 0.1$ . For  $\gamma_4 = 0.5$ ,  $u_1 = u_2$ , the positions of the steps from both modes coincide, the height of each step is the sum of the two contributions. Normalization of the current  $I_0 = 16 e \Gamma_{1,r} \int_{-r}^r (E_F) dx$ . Inset: the velocities of plasmon modes  $u_1$  and  $u_2$  vs  $\gamma_4$ . Other parameters:  $g_1 = 0.28$ ,  $g_2 = 0.26$ ,  $\alpha = 0.05$ .
