**Abstract.**

Colloidal suspensions and polyelectrolyte solutions containing multivalent counterions can exhibit some very counter-intuitive behavior usually associated with the low temperature physics. There are two particularly striking phenomena resulting from strong electrostatic correlations. One is the like-charge attraction and the second is the polyion overcharging. In this contribution we will concentrate on the problem of overcharging. In particular we will explore the kinetic limitation to colloidal charge inversion in suspensions containing multivalent counterions.

## 1. Introduction

Colloidal suspensions and polyelectrolyte solutions containing multivalent counterions can exhibit some very curious electrostatic behavior [1]. It is found that under some circumstances two like-charged polyions inside suspension can actually attract one another [2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16]. The counterion mediated attraction is responsible for the *DNA* compaction inside the bacteriophages, viruses that infect bacteria [17, 18], and for the organization of eukaryotic cytoskeleton [19]. Another “strange” electrostatic behavior which can occur in suspensions containing multivalent counterions is the reversal of the electrophoretic mobility [1, 20, 21, 22, 23, 24, 25]. The first thing that is learned in a course on electrostatics is that the force produced by the electric field on a charged particle is

$$\mathbf{F} = QE . \tag{1}$$

Thus, a positively charged particle,  $Q > 0$ , is expected to move in the direction of the applied field while a negatively charged particle,  $Q < 0$ , will move in the direction opposite to the field. This simple picture, however, breaks down inside colloidal suspensions of low dielectric solvent or even in aqueous suspensions containing multivalent counterions. The reason for the violation of the “simple” physics learned in high-school are the strong electrostatic many-body interactions between the colloidal particles and the counterions. The reversal of electrophoretic mobility can be understood as a combination of two electrostatically driven mechanisms. Strong electrostatic interaction between colloids and counterions leads to formation of polyion-counterion complexes [26, 27, 28]. The existence of counterion condensation has been known for over thirty years [29, 30, 31], the general phenomenon is, however, much older than this and can be traced to the pioneering work of Bjerrum on ionic association inside electrolyte solutions almost 80 years ago [32]. In aqueous suspensions with only monovalent counterions, the net charge of complexes is of the same sign as the bare charge of polyions.

If the solvent is water and the counterions are monovalent, the electrostatic interactions between the condensed counterions can be neglected [1], and the simplest Poisson-Boltzmann theory is sufficient to describe the polyion-counterion complexation [26, 33]. In aqueous suspensions containing multivalent counterions or in suspension of low dielectric solvents, the electrostatic energy between the condensed counterions is significantly larger than the thermal energy and the electrostatic correlations between the condensed counterions can no longer be neglected. These electrostatic correlations can lead to colloidal overcharging i.e. the net charge of the complex is of opposite sign to the charge of the bare polyion. The overcharged colloid will then move in the “wrong” direction with respect to the applied electric field [1, 25].

## 2. Overcharging

To understand the phenomenon of overcharging we shall start by studying a very simple model. Consider a sphere of radius  $a$  and fixed charge  $-Zq$  distributed uniformly over its surface. We would like to know how many point-like  $\alpha$ -valent counterions, each of charge  $\alpha q$ , should be placed on top of this sphere in order to minimize the total electrostatic free energy [34, 1, 22, 24]. When we say “counterions” we have in mind both simple multivalent ions such as  $Ca^{++}$ , as well as more complicated micelle-like aggregates with  $\alpha$  significantly higher than one.

The free energy of a complex can be written as

$$E_n = \frac{Z^2 q^2}{2\epsilon a} - \frac{Z\alpha n q^2}{\epsilon a} + F_n^{\alpha\alpha} . \quad (2)$$

The first term is the self energy of the charged sphere, the second term is the electrostatic energy of interaction between the sphere and  $n$  condensed  $\alpha$ -ions, and the last term is the electrostatic energy of repulsion between the condensed counterions. To calculate the free energy of repulsion, it is convenient to express  $F_n^{\alpha\alpha}$  in terms of the free energy of a one component plasma (*OCP*),  $n$   $\alpha$ -ions on the surface of a sphere with a uniform *neutralizing* background,  $F_n^{OCP}$ . The free energy of a spherical *OCP* can be written as

$$F_n^{OCP} = F_n^{\alpha\alpha} - \frac{\alpha^2 n^2 q^2}{\epsilon a} + \frac{\alpha^2 n^2 q^2}{2\epsilon a} . \quad (3)$$

Substituting Eq. (3) into Eq. (2) the electrostatic free energy of a polyion-counterion complex becomes,

$$E_n = \frac{(Z - \alpha n)^2 q^2}{2\epsilon a} + F_n^{OCP} . \quad (4)$$

In the strong coupling limit, corresponding to multivalent counterions or solvents of low dielectric permittivity, the free energy of the *OCP* is well approximated by the free energy of the low temperature phase corresponding to a triangular Wigner crystal,

$$F_n^{OCP} = -M \frac{\alpha^2 q^2 n^{3/2}}{2\epsilon a} . \quad (5)$$

where  $M$  is the Madelung constant. For weaker couplings, the expression for the  $F_n^{OCP}$  can be obtained from the fits to the Monte Carlo data [35]. For concreteness we shall use  $M = 1.106$ , the value appropriate for a planar Wigner crystal [1].

The effective charge of a polyion-counterion complex, in units of  $-q$  is

$$Z_{eff} = Z - \alpha n , \quad (6)$$

The optimum number of condensed counterions is determined from the minimization of the total electrostatic free energy. We find [22, 24, 1]

$$Z_{eff}^* = -\frac{1 + \sqrt{1 + 4\gamma^2 Z}}{2\gamma^2} \approx -\frac{\sqrt{Z}}{\gamma} , \quad (7)$$

where

$$\gamma = \frac{4}{3M\sqrt{\alpha}} . \quad (8)$$

We see that the optimal charge of a polyion-counterion complex is of opposite sign to the bare colloidal charge, i.e. the complex is overcharged. Inside the colloidal suspension containing multivalent counterions or solvents of low dielectric permittivity the electrophoretic mobility can, therefore, be reversed.

Some care, however, must be taken in extrapolating the results of this simple model to real systems. While we have treated the counterions as condensed on top of the sphere, this is clearly not the case for real colloidal suspension. Instead the associated counterions form a layer around a colloidal particle which can be some nanometers wide. The presence of simple electrolyte also strongly affects the net charge of the polyion- $\alpha$ -ion complex. Furthermore, the complex formation is a kinetic phenomenon requiring a counterion to overcome an energy barrier in order to join the already overcharged complex.

### 3. The overcharging potential

In the previous section we found that the minimum of the total electrostatic free energy of a polyion- $\alpha$ -ion complex corresponds to an overcharged state. However, for a counterion to join an already overcharged complex it must overcome an energy barrier. The waiting time for a thermal fluctuation of sufficient strength necessary to drive a counterion over an activation barrier scales exponentially with the height of the barrier. There is, therefore, a kinetic limitation to the degree of overcharging which can prevent a thermodynamically optimum state from being reached on experimental time scale. To explore this further we have to construct an effective interaction potential between a complex and a counterion separated by distance  $r$ .

The work necessary to bring a counterion from infinity to join a complex containing  $n$   $\alpha$ -ions is

$$W = \frac{dE_n}{dn} . \quad (9)$$

We define the reduced electrostatic potential of a counterion on the surface of the complex as  $\varphi(a) = \beta W$ , where  $\beta = 1/k_B T$ . Differentiating Eq. (4) we find

$$\varphi(a) = -\frac{(Z - \alpha n)\lambda_B \alpha}{a} - \frac{3M\alpha^2 \sqrt{n}}{4a} , \quad (10)$$

where  $\lambda_B = q^2/\epsilon k_B T$ . The first term of Eq. (10) is the electrostatic energy of interaction between a uniform spherical charge and an  $\alpha$ -ion, while the second term is due to electrostatic correlations between the  $\alpha$ -ions. In the strong coupling limit correlational contribution to the interaction potential decay exponentially fast with the separation from the polyion surface [7, 15, 36]. The characteristic length is set by the average separation between the condensed counterions. More specifically we can approximate the reduced interaction potential by

$$\varphi(r) = -\frac{(Z - \alpha n)\lambda_B \alpha}{r} - \frac{3M\alpha^2 \sqrt{n}}{4a} e^{-(r-a)/\xi} . \quad (11)$$

The decay of the correlational contribution is governed by the characteristic length  $\xi$  which in the strong coupling limit is well approximated by [7, 15, 36],

$$\xi = \frac{1}{|\mathbf{G}|}, \quad (12)$$

where  $\mathbf{G}$  is the reciprocal lattice vector of a triangular Wigner crystal of condensed counterions. Due to strong coupling between the condensed counterions, Eq. (12) should remain a good approximation even significantly above the crystallization temperature. For a triangular Wigner crystal,

$$|\mathbf{G}| = \frac{4\pi}{\sqrt{3}b}, \quad (13)$$

where  $b$  is the lattice spacing

$$b = \frac{1}{3^{1/4}\sqrt{\sigma}} \quad (14)$$

and  $\sigma = n/4\pi a^2$  is the surface density of condensed counterions. Substituting Eqs. (13) and (14) into Eq. (12), the decay length is found to be

$$\xi = \frac{3^{1/4}}{2\sqrt{\pi}} \frac{a}{\sqrt{n}}. \quad (15)$$

We are now in possession of the electrostatic potential which will allow us to study the kinetics of overcharging.

#### 4. Kinetics of overcharging

For  $n < Z/\alpha$ , the electrostatic potential between a counterion and a complex is purely attractive favoring further counterion condensation. Inside an electrolyte solution this tendency towards polyion-counterion association is opposed by the loss of entropy resulting from the confinement of condensed counterions near the colloidal surface. Here, however, we shall not be concerned with the role of entropy [1].

For  $n > Z/\alpha$  the interaction potential has two minima, one located at  $r = a$  and the second at  $n = \infty$ . For  $Z/\alpha < n < n^*$  the  $r = a$  minimum is the dominant one, while for  $Z > n^*$  the global minimum changes to  $r = \infty$ . The value of  $n^*$  corresponds to the number of condensed counterions which minimize the electrostatic free energy of the complex Eq. (4),

$$n^* = \frac{Z - Z_{eff}^*}{\alpha}. \quad (16)$$

In the case of trivalent counterions the energy barrier that a counterion needs to overcome in order to join a complex which already contains  $n^*$  condensed  $\alpha$ -ions is less than  $2k_B T$ , Fig 1. Thus, for trivalent counterions there is no kinetic hindrance to reaching the optimum overcharged state.

We next look at the height of the activation barrier as a function of the counterion valence, Fig. 2. It is clear that the height of the activation barrier grows rapidly with the increased valence of the  $\alpha$ -ions. In particular we see that for  $\alpha = 10$  the activation barrier

**Figure 1.** The reduced interaction potential between a complex of  $Z = 4000$ ,  $a = 1000$  Å,  $n = n^*$  condensed trivalent counterions, and a trivalent counterion located at distance  $r$  from the center of colloid.

**Figure 2.** The height of the activation barrier that an  $\alpha$ -ion must overcome to join an optimally overcharged complex composed of a colloid with  $Z = 4000$ ,  $a = 1000$  Å and  $n = n^*$  condensed  $\alpha$ -ions.

is already some  $10k_B T$  which is probably the maximum height that a counterion can overcome on a reasonable experimental time scale. Thus, the process of overcharging by the  $\alpha$ -ions with  $\alpha > 10$  will be kinetically controlled. For example, from Eq. (7) we see that the optimal state of overcharging of a colloidal particle of  $Z = 4000$  and radius  $a = 1000$  Å by micelles with  $\alpha = 25$  corresponds to  $Z_{eff}^* = -271$ . In practice, though, the process of overcharging will come to a stop when the barrier height reaches about  $10k_B T$ , implying that the complex will stop growing when the net charge is only  $Z_{eff} = -70$ .

## 5. Conclusion

In this contribution we have explored the kinetic limitation to overcharging. We find that kinetics does not play an important role for overcharging by simple multivalent counterions, so that the state of optimal overcharging, Eq. (7), is accessible within an experimental time scales. On the other hand, we find that the activation barrier grows rapidly with the valence of counterions, suggesting that the extent of overcharging by micelle-like aggregates is largely kinetically controlled.

The kinetic limitation to overcharging might also be important for the formation of the DNA-cationic lipid complexes. The problem of a reliable and safe mechanism for gene delivery is particularly pressing in view of the current medical applications. Strong electrostatic repulsion between a DNA and a cellular membrane inhibits transfection of a naked DNA into the cell. A way to overcome this difficulty is through the formation of overcharged complexes between the DNA and the cationic liposomes [37, 38, 39, 40, 41]. These lipoplexes having a net positive charge are attracted to the cellular membrane, facilitating the genetic transfection.

Finally, the presence of a simple electrolyte will have a strong influence on the overcharging. It has been demonstrated that for sufficient concentration of  $\alpha$ -ions, monovalent salt favors overcharging [42, 1]. In fact in the presence of simple electrolyte the thermodynamic state of optimum overcharging corresponds to the charge inversion of as much as 100%. This should be contrasted with the result of Eq. (7), which shows that in the absence of salt, the effective charge of a complex scales as a square root of the bare charge. The presence of salt will also lower the height of the activation barrier reducing the kinetic hindrance to overcharging.
