#### (D ated: 0 ctober 28, 2002)

It is now widely accepted that the cuprate superconductors are characterized by the same longrange order as that present in the Bardeen-Cooper-Schrie er (BCS) theory: that associated with the condensation of Cooper pairs. The author argues that m any physical properties of the cuprates require interplay with additional order parameters associated with a proxim ate M ott insulator. A classi cation of M ott insulators in two dimensions is proposed. Experimental evidence so far shows that the class appropriate to the cuprates has collinear spin correlations, bond order, and con nement of neutral, spin S = 1=2 excitations. P roxim ity to second-order quantum phase transitions associated with these orders, and with the pairing order of BCS, has led to system atic predictions for m any physical properties. In this context the author reviews the results of recent neutron scattering, uxoid detection, nuclear m agnetic resonance, and scanning tunnelling m icroscopy experiments.

#### I. INTRODUCTION

The discovery of high temperature superconductivity in the cuprate series of compounds by Bednorz and Muller (1986) has strongly in uenced the development of condensed matter physics. It stimulated a great deal of experim ental work on the synthesis and characterization of a variety of related interm etallic compounds. It also reinvigorated theoretical study of electronic systems with strong correlations. Technological applications of these materials have also appeared, and could become more widespread.

Prior to this discovery, it was widely assumed that all known superconductors, or super uids of neutral ferm ions such as <sup>3</sup>He, were described by the theory of Bardeen, Cooper and Schrie er (BCS) (Bardeen et al., 1957). Certainly, the quantitative successes of BCS theory in describing an inpressive range of phenom ena in the lower temperature superconductors make it one of them ost successful physical theories ever proposed. Soon after the discovery of the high temperature superconductors, it became clear that m any of their properties, and especially those at temperatures (T) above the superconducting critical temperature (T<sub>c</sub>), could not be quantitatively described by the BCS theory. O versom ing this failure has been an important motivation for theoretical work in the past decade.

One of the purposes of this article is to present an updated assessment of the applicability of the BCS theory to the cuprate superconductors. W e will restrict our attention to physics at very low tem perature associated with the nature of the ground state and its elementary excitations. This will allow us to focus on sharp, qualitative distinctions. In particular, we will avoid the regime of tem peratures above T<sub>c</sub>, where it is at least possible that any failure of the BCS theory is a symptom of our inability to make accurate quantitative predictions in a strong coupling regime, rather than our having missed a qualitatively new type of order. A lso, while this article will present a unied view of the important physics of the cuprate superconductors, it is not a comprehensive review, and it does not attempt to relect the state of the eld by representing the variety of view points that have been taken elsewhere in the literature.

The primary assertions of this article are as follows. At the lowest energy scales, the longest length scales, in

E lectronic address: subir.sachdev@ yale.edu

the absence of strong external perturbations, and at bptim al' carrier concentrations and above, all experim ental indications are that the cuprate superconductors can indeed be described in the fram ework of the BCS theory: the theory correctly captures the prim ary order param eter of the superconducting state, and the quantum num bers of its elementary excitations. However, many experim ents at lower doping concentrations and at shorter length scales require one or more additional order param eters, either conventional (i.e. associated with the breaking of a sym m etry of the H am iltonian) or topological' (see Section III.B.2 below). These order parameters are best understood and classi ed in terms of the physics of \M ott insulators," a topic which will be discussed in greater detail below. The importance of the Mott insulator was stressed by Anderson (1987). Our understanding of M ott insulators, and of their classi cation into categories with distinct physical properties has advanced greatly in the last decade, and a sharper question of experim ental relevance is: which class of M ott insulators has its order' present in the cuprate superconductors? A swe shall discuss below, the evidence so far supports a class quite distinct from that implied in Anderson's proposal (Sachdev and Read, 1991).

How can the postulated additional order parameters be detected experimentally? In the simplest case, there could be long-range correlations in the new order in the ground state: this is apparently the case in La<sub>2</sub> Sr CuO<sub>4</sub> at low carrier concentrations, and we will describe recent experiments which have studied the interplay between the new order and superconductivity. However, the more common situation is that there are no long range correlations in any additional order param eter, but the 'uctuating' order is nevertheless in portant in interpreting certain experiments. A powerful theoretical approach for obtaining sem i-quantitative predictions in this regime of uctuating order is provided by the theory of quantum phase transitions: in agine that we are free to tune param eters so that ultim ately the new order does acquire long range correlations som ewhere in a theoretical phase diagram. A quantum critical point will separate the phases with and without long-range order: identify this critical point and expand away from it towards the phase with uctuating order, which is the regim e of experim ental interest (Chubukov et al., 1994a; Sachdev and Ye, 1992); see Fig 1. An illum inating discussion of uctuating order near quantum critical points (along with a thorough analysis of many recent experiments which has some overlap with our discussion here) has been provided recently by K ivelson et al. (2002a).

An especially important class of experiments involve perturbations which destroy the superconducting order of the BCS state locally (on the scale a few atom ic spacings). Under such situations the theory outlined above predicts that the order of the M ott insulator is revealed in a halo surrounding the perturbation, and can, in principle, be directly detected in experiments. Perturbations of this type are Zn impurities substituting on the Cu sites, and

FIG.1 Our theoretical strategy for describing the in uence of a new order parameter in a BCS superconductor. Here q is som e convenient coupling constant in the H am iltonian, and we im agine that the superconductor of physical interest is a BCS superconductor with  $g > g_c$ . Theoretically, it is useful to in agine that we can tune g to a value sm aller than  $g_c$  where there are long-range correlations in a new order param eter. Having identied and understood the quantum phase transition at  $g = g_c$ , we can expand away from it back towards the BCS superconductor (as indicated by the thick arrow) to understand the in uence of quantum uctuations of the new order parameter. This approach is most e ective when the transition at  $q = q_c$  is second order, and this will usually be assum ed in our discussion. Note that the horizontal axis need not be the concentration of m obile carriers, and it m ay well be that the superconductor of physical interest does not exhibit the g <  $g_{\rm c}$  state at any carrier concentration.

the vortices induced by an applied magnetic eld. W e shall discuss their physics below .

To set the stage for confrontation between theory and experiment, we review some essential features of the BCS theory in Section II, and introduce key concepts and order parameters in the theory of M ott insulators in Section III. We will combine these considerations in our discussion of doped M ott insulators in Section IV, which will also include a survey of some experiments. A theoretical phase diagram which encapsulates much of the physics discussed here appears in Section IV, while Section V I concludes with a discussion on possible directions for future work.

### II. BCS THEORY

In BCS theory, superconductivity arises as an instability of a metallic Ferm i liquid. The latter state is an adiabatic continuation of the free electron model of a metal, in which all single particle states, labeled by the B loch crystalm om entum  $\tilde{K}$ , inside the  $\tilde{K}$ -space Ferm isurface are occupied by electrons, while those outside rem ain empty. W ith  $c_{\tilde{K}}^{y}$  the creation operator for an electron with momentum  $\tilde{K}$  and spin projection = "#, a reasonable description of the Ferm i liquid is provided by the free electron H am iltonian

$$H_{0} = \bigvee_{k}^{X} ("_{k}) c_{k}^{Y} c_{k}; \qquad (1)$$

where " $_{k}$  is the energy-momentum dispersion of the single-particle B loch states and is the chemical potential; the locus of points with " $_{k}$  = denes the Ferm i

surface. Changes in electron occupation numbers near the Ferm i surface allow low energy processes which are responsible for the conduction properties of m etals.

BCS realized that an arbitrarily weak attractive interaction between the electrons would induce the electrons near the Ferm i surface to lower their energy by binding into pairs (known as Cooper pairs) (Cooper, 1956). BCS also proposed a mechanism for this attractive interaction: the exchange of a low energy phonon between two electrons, along with the rapid screening of the repulsive C oulom b interaction by the other electrons, leads to a residual attractive interaction near the Ferm i surface. We regard this mechanism of electron pairing as a specic sidelight of BCS theory for good metals, and not an essential characterization of the BCS state. Indeed in liquid <sup>3</sup>He, the pairing is believed to arise from exchange of spin uctuations ('param agnons'), but the resulting super uid state has many key sim ilarities to the superconducting m etals.

In the BCS ground state, the Cooper pairs undergo a process of condensation which is very closely related to the Bose-Einstein condensation of non-interacting bosons. Two well separated Cooper pairs obey bosonic statistics when adiabatically exchanged with each other, but their behavior is not simply that of point-like Bose particles when their internal wavefunctions overlap the constituent electrons become important at these short scales; however it is the long distance bosonic character which is crucial to the appearance of a condensate of Cooper pairs. In the original Bose-Einstein theory, the zero m om entum boson creation operator can be replaced by its c-num ber expectation value (due to the occupation of this state by a macroscopic number of bosons); sim ilarly, the BCS state is characterized by the expectation value of the creation operator of a Cooper pair with zero center of m ass m om entum :

The functional form of (2) in spin and K-space carries inform ation on the internal wavefunction of the two electrons form ing a Cooper pair: we have displayed a spinsinglet pair with a d-wave orbital wavefunction on the square lattice, as is believed to be the case in the cuprates (Scalapino, 1995; T suei and K intley, 2000).

A long with (2) as the key characterization of the ground state, BCS theory also predicts the elementary excitations. These can be separated into two types: those associated with the motion of center of mass, R, of the C ooper pairs, and those in which a pair is broken. The center of mass motion (or super ow) of the C ooper pairs is associated with a slow variation in the phase of the pairing condensate  $_0 ! _0 e^{i (R)}$ : the superconducting ground state has (R) = a constant independent of R (and thus long-range order in this phase variable), while a slow variation is one in which this phase has a non-trivial winding, while the super ow has a non-zero circu-

lation:

$$d\mathbf{\hat{R}} = 2 \mathbf{n}$$
(3)

where  $n_v$  is the integer-valued vorticity, and C is a contour enclosing the vortex core. A standard gauge invariance argument shows that each such vortex must carry a total magnetic ux of  $n_vhc=(2e)$ , where the 2e in the denom inator represents the quantum of charge carried by the \bosons" in the condensate. Excitations which break C ooper pairs consist of multiple S = 1=2 ferm ionic quasiparticles with dispersion

$$E_{k} = \frac{q}{\left(\frac{k}{k}\right)^{2} + j_{k}^{2}}; \qquad (4)$$

and these reduce to the particle and hole excitations around the Ferm i surface when  $_0$  ! 0.

All indications from experiments so far are that the cuprate superconductors do have a ground state characterized by (2), and the elementary excitations listed above. However, BCS theory does make numerous other predictions which have been successfully and thoroughly tested in the low temperature superconductors. In particular, an important prediction is that if an external perturbation succeeds in destroying superconductivity by sending  $j_0 j!$  0, then the parent Ferm i surface, which was swallowed up by the C ooper instability, would reappear. This prediction is quite di erent from the perspective discussed earlier, in which we argued for the appearance of a halo of order linked to the M ott insulator.

#### III. MOTT INSULATORS

The B loch theory of metals also specified conditions under which crystalline materials can be insulating: if, after lling the lowest energy bands with electrons, all bands are either fully occupied or completely empty, then there is no Ferm i surface, and the system is an insulator. However, some materials are insulators even though these conditions are not satistical, and one-electron theory would predict partially lled bands: these are M ott insulators. Correlations in the motion of the electrons induced by their C oulom b interactions are crucial in preventing metallic conduction.

O ne of the parent compounds of the cuprate superconductors,  $La_2CuO_4$ , is a simple example of a M ott insulator. The lowest energy electronic excitations in this m aterial reside on the Cu  $3d_{x^2 y^2}$  orbitals, which are located on the vertices of a square lattice. The crystal has a layered structure of stacked square lattices, with only a weak am plitude for electron hopping between successive layers. (W e shallneglect the interlayer coupling and focus on the physics of a single square lattice in the rem ainder of this article.) A fler accounting for the ionization states of the other ions in  $La_2CuO_4$ , there turns out to be exactly one electron per unit cell available to occupy the Cu  $3d_{x^2 y^2}$  band. W ith two available spin states, this

FIG. 2 M otion of the two ferrom agnetically aligned spins in (a) is prohibited by the Pauli principle. In contrast, the antiferrom agnetically aligned spins at the top and bottom in (b) can access a high energy interm ediate state (shown in the middle of (b)) and so undergo an exchange process.

band can accomm odate two electrons per unit cell, and so is half-lled, and should have a metallic Ferm isurface. Nevertheless,  $La_2CuO_4$  is a very good insulator. The reason for this insulating behavior can be understood quite easily from a simple classical picture of electron motion in the presence of the Coulom b interactions. Classically, the ground state consists of one electron localized on each of the  $3d_{x^2 \ y^2}$  orbitals: this statem inimizes the repulsive Coulom b interaction energy. Any other state would have at least one orbital with two electrons, and one with no electrons: there is a large energetic penalty for placing two electrons so close to each other, and this prohibits motion of electrons across the lattice: hence the M ott insulator.

Let us now look at the quantum theory of the M ott insulator more carefully. W hile charge uctuations on each site are expensive, it appears that the spin of the electron can be rotated freely and independently on each site. However, in the quantum theory virtual charge uctuations do occur, and these lead to residual \super-exchange" interactions between the spins (A nderson, 1959). We represent the spin on the Cu site j by the S = 1=2 spin operator S<sub>j</sub>; the elective H am iltonian that describes the spin dynam ics then takes the form

$$H = \int_{\substack{i < j}}^{X} J_{ij}S_i \quad S + \dots \quad (5)$$

where the  $J_{ij}$  are short-ranged exchange couplings and the ellipses represent possible multiple spin couplings, all of which preserve full SU (2) spin rotation invariance. Because the Pauli principle completely prohibits charge uctuations between two sites if they have parallel spin electrons, while they are only suppressed by the C oulom b repulsion if they have opposite spins (see F ig 2), we expect an antiferrom agnetic sign  $J_{ij} > 0$ , so that nearby spins prefer opposite orientations. C lassifying quantum ground states of m odels like (5) is a problem of considerable complexity, and has been the focus of extensive research in the last decade.  ${\tt W}$  e sum  ${\tt m}$  arize the current understanding below .

In keeping with the spirit of this article, we characterize ground states of H by a number of distinct order param eters. We only discuss states below which have longrange correlation in a single order parameter; in most cases, co-existence of multiple order parameters is also allowed (Balents et al., 1999; Senthil and Fisher, 2000), but we will ignore this com plexity here. Our list of order parameters is not exhaustive, and we restrict our attention to the most plausible candidates (in the author's opinion) for short-range  $J_{ij}$ .<sup>1</sup>

A lthough our discussion below will refer mainly to M ott insulators, we will also mention ground states of non-insulating systems with mobile charge carriers: the order parameters we use to characterize M ott insulators can be applied more generally to other system s, and this will done in more detail in Section IV.

## A. M agnetically ordered states

Such states are obtained by examining H for the case of large spin S on each site: in this limit, the S<sub>j</sub> can be taken as classical c-numbers, and these take a denite non-zero value in the ground state. M ore precisely, the SU (2) spin rotation symmetry of H is spontaneously broken in the ground state by the non-zero values of hS<sub>j</sub>i, which are chosen to minimize the energy of H . We consider only states without a net ferrom agnetic moment ( $_{j}hS_{j}i=0$ ), and this is expected because  $J_{ij} > 0$ . The pattern of non-zero hS<sub>j</sub>i can survive down to S = 1=2, and this is often found to be the case, although quantum uctuations do signi cantly reduce the magnitude of hS<sub>j</sub>i.

An especially important class of magnetically ordered states<sup>2</sup> is characterized by a single ordering wavevector

<sup>&</sup>lt;sup>1</sup> An order that has been much discussed in the literature, which we do not discuss here, is that associated with the staggered ux state (A eck and M arston, 1988), and the related algebraic spin liquid (R antner and W en, 2001; W en, 2002a). The low energy theory of these states includes a gapless U (1) gauge eld, and it has been argued (Sachdev and Park, 2002) that instantons, which are allowed because the underlying lattice scale theory has a compact gauge sym metry, always proliferate and render these unstable towards con ning states (of the type discussed in Section III.B.1) in two spatial dimensions. However, states with a gapless U (1) gauge eld are allowed in three spatial dimensions (M otrunich and Senthil, 2002; W en, 2002b).

<sup>&</sup>lt;sup>2</sup> M agnetically ordered states with the values of hS<sub>j</sub> i non-coplanar (i.e. three dimensional spin textures) are not included in this sim ple classi cation. Their physical properties are expected to be sim ilar to those of the non-collinear case discussed in Section IIIA 2 in that quantum uctuations of such a state lead to a param agnet with topological order. How ever, this param agnet is likely to have also a broken tim e-reversal sym m etry.

FIG.3 States with collinear m agnetic order on a square lattice with unit lattice spacing and wavevectors (a) K = (;), (b) and (c) K = (3 =4; ). Shown are the values of (6) on the square lattice sites  $r_{\rm j}$ . A single unit cell is shown for the latter two states; they are crystographically inequivalent and have di erent re ection planes: in (b) the re ection planes are on certain sites, while in (c) they are at the midpoint between two sites.

Кĩ:

$$hS_{j}i = N_{1}\cos \kappa + N_{2}\sin \kappa + (6)$$

where  $r_j$  is the spatial location of the site j, and N  $_{1;2}$  are two xed vectors in spin space. We list two key subcategories of m agnetically ordered M ott insulators which obey (6):

#### 1. Collinear spins, N<sub>1</sub> N<sub>2</sub> = 0

In this situation, the mean values of the spins in (6) on all sites j are either parallel or anti-parallel to each other. The undoped insulator  $La_2CuO_4$  is of this type<sup>3</sup> with K = (;); see Fig 3a. Insulating states with static holes appeared in Zaanen and Gunnarsson (1989), Machida (1989), Schulz (1989), and Poilblanc and Rice (1989) with ordering wavevectors which move continuously away from (;). Another important illustrative example is the case K = (3 = 4;). Such a wavevector could be preferred in a M ott insulator by longer range  $J_{ij}$ in (5), but in practice it is found in a non-insulating state obtained by doping  $La_2CuO_4$  with a suitable density of

FIG. 4 A state with non-collinear magnetic order on the square lattice de ned by (6) and (7) with wavevector K = (3 = 4; ).

m oble carriers (K ivelson and Em ery, 1996; M artin et al., 2000; Seibold et al., 1998; Tranquada et al., 1995; W akim oto et al., 2001, 1999; W hite and Scalapino, 1998a, b, 1999) | we can crudely view the mobile carriers as having induced an elective longer range exchange between the spins. Two examples of states with this value of K are shown in Fig 3, a site-centered state with  $N_2 = 0$  in Fig 3b, and a bond-centered state with  $N_2 = (2 1)N_1$  in Fig 3c. (The states have planes of relation symmetry located on sites and the centers of bonds respectively, and so are crystallographically inequivalent. A lso, these inequivalent classes are only present if the wavevector K is commensurate with the underlying lattice.)

#### 2. Non-collinear spins, N<sub>1</sub> N<sub>2</sub> $\in$ 0

Now the spin expectation values in (6) lie in a plane in spin space, rather than along a single direction. For sim plicity, we will only consider the sim plest, and most common, case of non-collinearly ordered state, in which

$$N_1 \quad N_2 = 0 ; \quad N_1^2 = N_2^2 \in 0;$$
 (7)

and then the values of  $hS_{ji}$  in ap out a circular spiral (Shraim an and Siggia, 1988, 1989), as illustrated in Fig 4.

#### B. Param agnetic states

The otherm a pr class of states com prises those having

$$hS_{j}i = 0; (8)$$

and the ground state is a total spin singlet.<sup>4</sup> Loosely speaking each spin  $S_j$  nds a partner, say  $S_{j^0}$ , and the two pair up to form a singlet valence bond

$$\frac{1}{\frac{p}{2}}(j"i_{j}j#i_{j^{0}} j#i_{j}j"i_{j^{0}}):$$
(9)

 $<sup>^3</sup>$  For this special value of K on the square lattice, and with the origin of r co-ordinates on a lattice site, (6) is actually independent of N  $_2$  )

<sup>&</sup>lt;sup>4</sup> In a nite system with an even number of spins, the magnetically ordered ground state also has total spin zero. However, to obtain a state which breaks spin rotation symmetry as in (6), it is necessary to mix in a large number of nearly degenerate states which carry non-zero total spin. The paramagnetic does not have such higher spin states available at low energy in a nite system.

FIG. 5 A crude variational wavefunction of a bond-ordered param agnetic state. The true ground state will have uctuations of the singlet bonds about the conguration shown here, but its pattern of lattice symmetry breaking will be retained. In other words, each bond represented by an ellipse above will have the same value of hQ a ( $r_j$ )i, and this value will be distinct from that associated with all other bonds. This pattern of symmetry breaking is represented more abstractly in Fig 6a.

O f course, there are many other choices for the partner of spin  $S_j$ , and in the Feynm an path integral picture we imagine that the pairing conguration uctuates in quantum imaginary time; this is the Yesonating valence bond' picture of Pauling (1949), Fazekas and Anderson (1974), and Anderson (1987). However, there is a great of structure and information contained in the manner in which this uctuation takes place, and research (Chubukov et al., 1994b,c; Read and Sachdev, 1991; Sachdev and Read, 1991) dilineating this structure has led to the following classi cation of paramagnetic M ott insulators.

#### 1. Bond-ordered states: con ned spinons

This class of states can be easily understood by the caricature of its wavefunction shown in Fig 5: here each spin has chosen its valence bond partner in a regular manner, so that there is a long-range 'crystalline' order in the arrangement of valence bonds. This ordering of bonds clearly breaks the square lattice space group sym metries under which the Hamiltonian is invariant. Of course, the actual wavefunction for any realistic Ham iltonian will have uctuations in its valence bond con guration, but the pattern of lattice sym metry breaking im plied by Fig 5 will be retained in the true bond-ordered ground state. We can make this precise by examining observables which are insensitive to the electron spin direction: the sim plest such observables we can construct from the low energy degrees of freedom of the M ott insulator are bond variables, which are a measure of the exchange energy between two spins:

$$Q_a(\mathbf{r}_j) \quad S_j \quad S_a:$$
 (10)

Here a denotes displacement by the spatial vector  $\mathbf{r}_a$ , and so the spins above are at the spatial locations  $\mathbf{r}_j$  and  $\mathbf{r}_j + \mathbf{r}_a$ . We will mainly consider bond order with  $\mathbf{r}_a \in \mathbf{0}$ , but note that the on-site variable  $Q_0(\mathbf{r}_j)$ , with  $\mathbf{r}_a = \mathbf{0}$ , is

FIG. 6 Pattern of the bond variables  $hQ_a(r_j)i$ , for  $r_a$  a nearest-neighbor vector, in a number of param agnetic states with  $hS_ji = 0$ . For each state, the values of  $hQ_a(r_j)i$  are equal on bonds represented by the same type of line, and unequal otherwise. The number of distinct values of  $hQ_a(r_j)i$  are (a) 3, (b) 2, (c) 5, and (d) 5. The unit cells of the ground states have sizes (a) 2 1, (b) 2 2, (c) 4 1, and (d) 4 4.

a m easure of the charge density  $^5$  on site  $r_{\rm j}$ , and so this special case of (10) m easures the \charge order."

The state introduced in F ig 5 can be characterized by the pattern of values of  $M_a(\mathbf{r}_i)$  i with  $\mathbf{r}_a$  a nearest neigh-

<sup>&</sup>lt;sup>5</sup> By (10),  $Q_0(\mathbf{r}_j) = S_j^2$ . A site with a spin has  $S_j^2 = 3=4$ , while a site with a hole has  $S_j^2 = 0$ , and we assume that doubly occupied sites are very rare. Thus  $S_j^2$ , and hence  $Q_0(\mathbf{r}_j)$  is seen to be linearly related to the charge density on site j.

bor vector, as shown in F ig 6a: notice there are 3 distinct values of hQ<sub>a</sub>  $(r_j)$  i and sym m etries of the states in F igs 5 and 6a are identical. W hile these 3 values are quite different in the trial state in F ig 5, their values in the actual ground state m ay be quite close to each other: it is only required that they not be exactly equal.

A nother closely related bond-ordered state, which has appeared in som e theories (A ltm an and A uerbach, 2002; D om bre and K otliar, 1989; R ead and Sachdev, 1989a; Sachdev and R ead, 1996), is shown in Fig 6b: here the bonds have a plaquette-like arrangem ent rather than colum nar, but, as we shall discuss below, the physical properties of all the states in Fig 6 are quite sim ilar to each other.

W e can also consider patterns of bond order with larger unit cells, and two important structures which have appeared in theories of doped M ott insulators (Vojta, 2002; Vojta and Sachdev, 1999) are shown in Figs 6c and 6d (related bond orders also appear in studies of quasi-onedim ensionalm odels appropriate to organic superconductors (Clay et al, 2002; M azum dar et al, 2000)). A gain, as in Section IIIA 1, such states could, in principle, also appear in M ott insulators with longer-range exchange in (5). An interesting property of these states is that, unlike the states in Fig 6a and 6b, not all sites are crystallographically equivalent. This means that on-site spinsinglet observables, such as the site charge density, will also have a spatial modulation from site to site. A subtlety is that the Ham iltonian (5) acts on a Hilbert space of S = 1=2 spins on every site, and so the charge density on each site is xed at unity. However, it must be rem embered that (5) is an e ective model derived from an underlying Hamiltonian which does allow virtual charge uctuations, and the site charge modulations in the states of Figs 6c and 6d will appear when it is properly computed in terms of the microscopic degrees of freedom . At the same time, this argument also makes it clear that any such modulation is suppressed by the repulsive Coulomb energy, and could well be di cult to observe, even in the doped antiferrom agnet. So the onsite variable, hQ<sub>0</sub> ( $r_1$ ) i = hS<sup>2</sup><sub>i</sub>i, will have a weak modulation in the states of Fig 6c and 6d when computed in the full H ibert space of the m odel with charge uctuations. Note, how ever, that the modulation in bond orders associated with  $Q_a(r_i)$ , with  $r_a \in 0$ , need not be sm all in the states in Fig 6, as such m odulations are not suppressed as e ectively by the Coulom b interactions.

The physicalm echanism inducing bond-ordered states such as those in Fig 6 is illustrated in the cartoon pictures in Fig 7. More detailed computations rely on a sem iclassical theory of quantum uctuations near a magnetically ordered state (Read and Sachdev, 1990). Remarkably, very closely related theories also appear from a very dierent starting point from duality mappings (Fradkin and Kivelson, 1990; Read and Sachdev, 1990) of \quantum dimermodels" (Rokhsar and Kivelson, 1988) of the param agnetic state. These computations show that spontaneous bond order invariably appears in the

FIG. 7 Bond order induced by quantum uctuations. Valence bonds gain energy by \resonating" in pairs (Anderson, 1987; Fazekas and Anderson, 1974; Pauling, 1949; Rokhsar and K ivelson, 1988); shown are resonances around the plaquette (i.e. square loop) marked with a star. For the regular bond-ordered con guration of valence bonds in (a), such resonance can occur not only around the plaquette marked with a star, but around ve additional plaquettes. In contrast, in (b), such a resonance is possible only around the plaquette marked with a star. This additional quantum \entropy" associated with (a) selects regular bond order in the ground state. More sophisticated considerations (which also allow valence bonds that do not connect nearest neighbor sites) show that this mechanism is especially e ective in two dimensions (Read and Sachdev, 1990; Sachdev and Park, 2002).

ground state in system swith collinear spin correlations in two spatial dimensions (R ead and Sachdev, 1990; Sachdev and Park, 2002). We will have more to say about this connection between and bond and collinear spin order in Section III.C.1.

We also mention here the \nem atic" states of K ivelson et al. (1998) in the doped M ott insulator. These can also be characterized by the bond order variables in (10). The symmetry of translations with respect to  $r_j$ is not broken in such states, but the values of  $hQ_a(r_j)$  i for symmetry-related values of  $r_a$  become unequal. For example,  $hQ_a(r_j)$  i has distinct values for  $r_a = (1;0)$  and (0;1). Such states also appear in certain insulating antiferrom agnets (Read and Sachdev, 1989a,b, 1990).

It also interesting to note here that the bond order vari $ab les Q_a(r_i)$  also have spatial modulations in some of the magnetically ordered states considered in Section IIIA (Zachar et al, 1998). It is clear from (10) that any broken lattice symmetry in the spin-rotation invariant quantity  $hS_{i}$  i will generate a corresponding broken symmetry in the bond variable  $hQ_a(r_j)$ i. Evaluating the form er using (6) we can deduce the following: (i) the  $\mathcal{K} = (;)$  state in Fig 3a and the spiral state in Fig 4 have  $hQ_a(r_j)i$  independent of  $r_j$ , and hence no bond order; (ii) the bond-centered m agnetically ordered state in Fig 3c has precisely the same pattern of bond order as the param agnetic state in Fig 6c; (iii) the site-centered m agnetically ordered state in F ig 3b has bond order with  $hQ_a(r_i) i r_i$ -dependent, but with a pattern distinct from any shown here this pattern of bond order is in principle also allowed for param agnetic states, but has so far not

FIG.8 Linear con ning potential between two neutral S = 1=2 spinons in a bond-ordered state. The line of valence bonds with dashed lines is out of alignment with the global bond order, and it costs a nite energy per unit length.

been found to be stable in various studies. Finally, note that in (ii) and (iii) the period of the bond order (four) is half that of the spin m odulation (eight) {this is easily seen to be a general relationship following from the correspondence hQ<sub>a</sub> ( $r_j$ )i hS<sub>j</sub>i hS<sub>a</sub>i + ::: in m agnetically ordered states, which with (6) in plies an  $r_j$ -dependent m odulation of the bond order with wavevector 2K . It is worth reiterating here that this last relationship should not be taken to im ply that there are no m odulations in hQ<sub>a</sub> ( $r_j$ )i when hS<sub>a</sub>i = 0: there can indeed be bond m odulations in a param agnet, as discussed in the other paragraphs of this subsection, and as is already clear from the sim ple wavefunction in Fig 5 | these will be important later for physical applications.

W e continue our exposition of param agnetic bondordered states by describing excitations with non-zero spin. These can be understood simply by the analog of cartoon wavefunction pictures drawn in Fig 5. To create free spins we have to break at least one valence bond, and this initially creates two unpaired, neutral, S = 1=2degrees of freedom (the \spinons"). We can ask if the spinons can be moved away from each other out to innity, thus creating two neutral S = 1=2 quasiparticle excitations. As illustrated in Fig 8, this is not the case: connecting the two spinons is a line of defect valence bonds which is not properly aligned with the global bond order, and these defects have a nite energy cost per unit length. This linearly increasing potential is quite analogous to that between a quark and an anti-quark in a meson, and the spinons (quarks) are therefore perm anently con ned (Read and Sachdev, 1989b). Moving two spinons apart from each other will eventually force the breaking of the defect line by the creation of another pair of spinons. The only stable excitation with nonzero spin therefore consists of a pair of spinons and carries spin S = 1. We will refer to this quasiparticle as a spin exciton as its quantum numbers and observable characteristics are quite similar to spin excitons found in sem iconductors and metals. The spin exciton is clearly the analog of a meson consisting of a quark and anti-quark pair.

A similar reasoning can be used to understand the inuence of static spinless in purities i.e. the consequences

FIG.9 C artoon wavefunction for 2 static spinless Zn impurities in a conning, bond-ordered state. It we attempt to construct a wavefunction only using singlet valence bonds, then just as in Fig 8, there will be defect line of singlet bonds which are not aligned with the global bond order, which will cost a nite energy per unit length. When the two Zn impurities are su ciently far apart, it will pay to restore the bond order in between the impurities, at the price of unpaired S = 1=2 moments, one near each impurity.

of rem oving a S = 1=2 spin from a xed site j in (5). Experim entally, this can be conveniently done by substituting a spinless  $Zn^{++}$  ion in place of an S = 1=2 C u ion. Them ain physicale ect can be understood from the cartoon wavefunction in F ig 9: it is convenient to imagine placing 2 Zn impurities, and then moving them apart out to in nity to deduce the physics in the vicinity of a single impurity. As in our discussion above for spinons, note that there will initially be a line of defect valence bonds connecting the two Zn impurities, but it will eventually pay to annihilate this defect line by creating two spinons and binding each to a Zn impurity. Thus each Zn impurity con nes a free S = 1=2 spinon in its vicinity, and this can be detected in experiments (F inkelstein et al., 1990).<sup>6</sup>

#### 2. Topological order: free spinons

This type of param agnet is the \resonating valence bond" (RVB) state (Anderson, 1987; Baskaran and Anderson, 1988; Fazekas and Anderson, 1974; K ivelson et al., 1987; M oessner and Sondhi, 2001; P auling, 1949) in which the singlet pairings uctuate in a liquid-like conguration,<sup>7</sup> in contrast to the crystalline arrangem ent in

<sup>&</sup>lt;sup>6</sup> In principle the Zn impurity could also bind an electron (with or without a spinon) but this is suppressed by the charge gap in a M ott insulator. Later, in Section IV C when we consider Zn impurities in d-wave superconductors, a related phenom enon appears in the form of the K ondo e ect.

 $<sup>^7</sup>$  In recent years, Anderson (2002) has extended the RVB concept to apply to doped M ott insulators at temperatures above  $T_{\rm c}$ . This extension is not in consonance with the classi cation of the present article. The topological order discussed in this subsection can only be de ned at T=0 in two spatial dimensions. The description at  $T>T_{\rm c}$  requires solution of a problem of quantitative di cultly, and with incoherent excitations, but without sharp distinctions between di erent states.

FIG.10 Topological order in a resonating valence bond state. Shown is one component of the wavefunction, with a particular pairing of the spins into local singlets: the actual wavefunction is a superposition over a very large number of such pairing con gurations. The number of valence bonds cutting the dashed line is an invariant modulo 2 over these pairing con qurations, as shown by the following simple argument. Any rearrangement of the valence bonds can be reached by repeated application of an elementary rearrangement between 4 spins: (1;2)(3;4) ! (1;3)(2;4) (here (i,j) denotes a singlet bond between Si and Sj). So it is su cient to check this conservation law for 4 spins: this is done easily by explicitly considering all di erent possibilities am ong spins 1,2,3,4 residing to the left/right of the dashed line. If the system has periodic boundary conditions along the horizontal direction, then this conservation law is violated, but only by rearrangem ents associated with loops which circum navigate the system s; these only occur with a probability which becomes exponentially small as the circum ference of the system increases.

Fig 5. Despite the apparent disorder' in the valence bond con guration in the ground state, there is actually a subtle topological order param eter which characterizes this type of M ott insulator (Bonesteel, 1989; K ivelson, 1989; Read and Chakraborty, 1989; Read and Sachdev, 1991; Rokhsar and Kivelson, 1988; Thouless, 1987; Wen, 1991), and which plays an important role in determ ining its excitation spectrum. The reader can see this in the context of the cartoon picture shown in Fig 10. Count the number of singlet valence bonds cutting the dashed line in this gure: this num ber will clearly depend upon the particular valence bond con guration chosen from the many present in the ground state, and one such is shown in Fig 10. However, as argued in the gure caption, the number of bonds cutting the dashed line is conserved modulo 2 between any two con gurations which dier only local rearrangements of valence bonds: the quantum number associated with this conservation is the topological order in the ground state.

A convenient and powerfuldescription of this topological order is provided by an elective model of the singlet sector form ulated as  $Z_2$  gauge theory (Read and Sachdev, 1991; Sachdev and Read, 1991; Senthil and Fisher, 2000; W en, 1991).<sup>8</sup> W elevery on a self-contained derivation of this  $Z_2$  gauge theory to Section IIIC 2 (see especially F ig 11): here, we show that such a gauge theory has similar topological properties. In a system with periodic boundary conditions (with the topology of a torus), the  $Z_2$  gauge theory has di erent sectors depending upon whether there is a  $Z_2$  ux piercing any of the holes of the torus (follow ing Senthil and F isher (2000), this  $Z_2$  ux is now commonly referred to as a \vison"). In the valence bond picture discussed in the previous paragraph, a vison changes the sign associated with every valence bond cutting a line traversing the system in the vison direction (the dashed line in F ig 9); in other words, the even and odd valence bond sectors mentioned above now have their relative signs in the wavefunction changed.

In addition to appearing in the holes of the torus, the vison can also appear as a singlet excitation within the bulk (K izelson, 1989; R ead and C hakraborty, 1989; R ead and Sachdev, 1991; Senthil and F isher, 2000). It is now a vortex excitation in the  $Z_2$  gauge theory, that requires a nite energy for its creation. We will see below in Section IIIC 2 that there is an alternative, and physically revealing, interpretation of this vortex excitation in terms of the order parameters used earlier to characterize the m agnetically ordered state, and that the topological order is intim ately connected to the vison energy gap.

Finally, we can describe the spin-carrying excitations of this topologically ordered state using the crude, but instructive, methods used in Section III.B.1. As there is no particular bond order associated with the ground state, the spinons have no con ning force between them, and are perfectly free to travel throughout the system as independent neutral S = 1=2 quasiparticles. Sim ilarly, there is no con ning force between Zn impurities and the spinons, and so it is not required that an S = 1=2 mom ent be present near each Zn impurity (Fendley et al., 2002; Sachdev and Vojta, 2000).

# C. Connections between m agnetically ordered and param agnetic states

A central ingredient in the reasoning of this article is the claim that there is an intimate connection between the magnetically ordered states in Section IIIA and a corresponding param agnetic state in Section IIIB. In particular, the collinear states of Section IIIA 1 are linked to the bond-ordered states in Section IIIB 1, while

 $<sup>^{8}</sup>$  Readers not fam iliar with Z  $_{2}\,$  gauge theories m ay understand

them by analogy to electrom agnetism. The latter is a U (1) gauge theory in which the physics is invariant under the transform ation z !  $e^{i}$  z, A ! A @ where z is some matter eld, A is a gauge eld, and is an arbitrary spacetime-dependent eld which generates the gauge transform ation. Similarly, in a Z<sub>2</sub> gauge theory, matter elds transform as z ! z, where is a spacetime-dependent eld which generates the gauge transform as z ! . The Z<sub>2</sub> gauge eld  $_{ij}$  resides on the links of a lattice, and transforms s as  $_{ij}$  ! i j j.

the non-collinear states of Section IIIA 2 are linked to the topologically ordered states of Section IIIB 2. The reader will nd a more technical discussion of the following issues in a companion review article by the author (Sachdev, 2003).

Before describing these links in the following subsections, we discuss the meaning of the \connectedness" of two states. The magnetically ordered phases are characterized by sim ple order param eters that we have discussed in Section IIIA. Now imagine a second-order quantum phase transition in which the magnetic longrange order is lost, and we reach a state with uctuating magnetic correlations, which is ultimately a rotationally invariant, spin-singlet param agnet at the longest length scales. We will review arguments below which show that this \quantum disordered" state (Chakravarty et al., 1989) is characterized by the order param eter of the connected param agnetic state i.e. uctuating collinear magnetic order leads to bond order, while uctuating non-collinear magnetic order can lead to topological order. So two connected states are generically proxim ate to each other, without an intervening rst order transition, in a generalized phase diagram drawn as a function of the couplings present in the Ham iltonian.

## 1. Collinear spins and bond order

It should be clear from Section IIIA.1 that collinear spin states are characterized by a single vector N<sub>1</sub>. The second vector N<sub>2</sub> is pinned to a value parallel to N<sub>1</sub> by som e short distance physics, and at long distances we may consider a theory of the uctuations of N $_1$  alone. In a phase with magnetic order, the dom inant spin-wave uctuations occur in con gurations with a xed non-zero value of  $\mathbb{N}_1$  j. In the transition to a non-m agnetic phase, the mean value of  $N_1$  j will decrease, until the uctuations of N<sub>1</sub> occur about N<sub>1</sub> = 0 in a param agnetic phase. There are 3 norm alm odes in this uctuation spectrum, corresponding to the 3 directions in spin space, and the resultant is an S = 1 gapped quasiparticle excitation in the param agnetic state. This we can easily identify as the S = 1 spin exciton of the bond-ordered state: this identi cation is evidence supporting our claim ed connection between the states of Section IIIA 1 and IIIB 1.

Further evidence is provided by detailed com putations which show the appearance of bond order in the regime where N<sub>1</sub> uctuations have lost their long-range order. We have already seen a simple example of this above in that the magnetically ordered state in Fig 3c already had the bond order of the param agnetic state in Fig 6c: it is completely natural for the bond order in the magnetically ordered phase in Fig 3c to persist across a transition in which spin rotation invariance is restored, and this connects it to the state in Fig 6c. A non-trivial example of a related connection is that between the K = (;)N eel state in Fig 3a, and the param agnetic bond-ordered states in Figs 6a and 6b, which was established by R ead and Sachdev (1989b), Read and Sachdev (1990), and Sachdev and Park (2002): Berry phases associated with the precession of the lattice spins were shown, after a duality m apping, to induce bond order in the phase in which long-range order in N $_1$  was lost.

### 2. Non-collinear spins and topological order

The rst argument of Section III.C. 1, when generalized to non-collinear spins, leads quite simply to a surprisingly subtle characterization of the associated param agnetic phase.

R ecall from Section IIIA 2 that the non-collinearm agnetic phase is characterized by two orthogonal, and equal length, vectors N<sub>1;2</sub>. It takes 6 real num bers to specify two vectors, but the 2 constraints in (7) reduce the num – ber of real parameters required to specify the ordered state to 4. There is a useful parameterization (C hubukov et al., 1994b,c) which explicitly solves the constraints (7) by expressing N<sub>1;2</sub> in term s of 2 com plex num bers  $z_*$ ,  $z_*$  (which are equivalent to the required 4 real num bers):

It can also be checked from (11) that  $(z_{*}; z_{*})$  transform s like an S = 1=2 spinor under spin rotations. So instead of dealing with a constrained theory of N<sub>1:2</sub> uctuations, we can express the theory in term s of the com plex spinor  $(z_{*}; z_{\#})$ , which is free of constraints. There is one crucial price we have to pay for this simpli cation: notice that the param etrization (11) is double-valued and that the spinors  $(z_{*}; z_{\#})$  and  $(z_{*}; z_{\#})$  both correspond to the same non-collinearly ordered state. Indeed, we can change the sign of z independently at di erent points in spacetime without changing the physics, and so any eective action for the  $(z_{*}; z_{\#})$  spinorm ust be obey a  $Z_2$  gauge invariance. Here is our rst connection with the topologically ordered param agnetic state of Section IIIB 2, where we had also discussed a description by a Z<sub>2</sub> gauge theory.

In the magnetically ordered non-collinear state we expect dom inant rotational uctuations about som e xed non-zero value N<sub>1</sub><sup>2</sup> = N<sub>2</sub><sup>2</sup> =  $(\dot{z}_{,,}\dot{z}_{,+}\dot{z}_{,+}\dot{z}_{,+}\dot{z}_{,-})^2$ . The constraint  $\dot{z}_{*}\hat{j} + \dot{z}_{\#}\hat{j} = constant$  de nes the surface of a sphere in a four-dimensional space  $(S_3)$  of magnetically ordered ground states de ned by the real and in aginary components of z, , z, . However, we need to identify opposite points on the sphere with each other, as  $(z_{*}; z_{\#})$ and ( z; z) are equivalent states: this identi es the order parameter space with  $S_3=Z_2$ . This quotient form has crucial consequences for the topological defect excitations that are permitted in both the magnetically ordered and the param agnetic phases. In particular, the order parameter space (see the review article by Mermin (1979)) allows stable  $Z_2$  vortices associated with the st hom otopy group  $_1$  (S<sub>3</sub>=Z<sub>2</sub>) = Z<sub>2</sub>: upon encircling such a

FIG. 11 A vison (Senthil and Fisher, 2000). On the left we show a circular path in real space; this path could be entirely within the bulk of the system (in which case it de nes a local vison excitation) or it encircles the entire system, which obeys periodic boundary conditions (so that now it de nes a global topological excitation). On the right is the space of magnetically ordered states represented by the com plex spinor ( $z_*; z_{\#}$ ) up to an overall sign. A swe traverse the real space circle, the path in order parameter space connects polar opposite points on S<sub>3</sub> (A and B), which are physically indistinguishable. A key point is that this vison excitation can be de ned even in a state in which magnetic order is lost: the path on the right will uctuate all over the sphere in quantum in aginary time, as will the location of the points A and B, but A and B will rem ain polar opposites.

vortex, we traverse a path in the order parameter space from  $(z_{"};z_{\#})$  to  $(z_{"};z_{\#})$ , as shown in Fig 11. A sargued in the caption, a fundamental point is that such vortices can be dened as sensible excitations even in the paramagnetic phase, where  $(z_{"};z_{\#})$  is strongly uctuating in quantum in aginary time: upon encircling the vortex, the path in order parameter space will also strongly uctuate, but will always connect polar opposite points on S<sub>3</sub>. We identify these param agnetic vortices with the visons of Section IIIB 2, thus rm ly establishing a connection between non-collinear magnetic order and the topologically ordered param agnet.

F inally, we wish to consider a Z<sub>2</sub> gauge theory in which magnetic order is lost continuously (Chubukov et al., 1994c; Read and Sachdev, 1991), and we obtain a paramagnetic phase in which the spinor  $(z_{*}; z_{*})$  uctuates about 0. A pedagogical description of such a theory was provided by Lammert et al. (1993) and Lammert et al. (1995) in an entirely di erent context: they considered therm alphase transitions in a nem atic liquid crystal, with order parameter  $S_2=Z_2$ , in three spatial dimensions. However their results can be transposed to the quantum phase transition in two spatial and one in aginary time dim ension of interest here, with the prim ary change being in the order parameter space from  $S_2=Z_2$  to  $S_3=Z_2$ : this change is only expected to modify uninteresting num erical factors in the phase diagram, as the global topologies of the two spaces are the same. As shown by Lammert et al. (1993) and Lam m ert et al. (1995), the m agnetically ordered state (with states labeled by points in  $S_{2;3}=Z_2$ ) does indeed undergo a continuous phase transition to a param agnetic state in which spin rotation invariance is restored and a topological order is present. This topological order arises because the  $Z_2$  visons discussed in F ig 11 do not proliferate in the param agnetic state; in this sense, the topological order here is sim ilar to the topological order in the low temperature phase of the classical X Y m odel in 2 dim ensions, where point vortices are suppressed below the K osterlitz-T houless transition (T houless, 1998). We can also connect the nonproliferation of visons to our discussion in Section III.B 2, where we noted that there was an excitation gap towards the creation of  $Z_2$  visons (Senthil and F isher, 2000). Indeed, an explicit connection between the topological order being discussed here and the topological order noted in the caption to F ig 10 was established by R ead and Sachdev (1991), Sachdev and R ead (1991), and Chubukov et al. (1994c).

M oreover, without the proliferation of visons in the ground state, the  $(z_*;z_{\#})$  con gurations can be de ned as single-valued con gurations throughout the sample. Norm alm ode oscillations of  $(z_*;z_{\#})$  about zero can now be identi ed as a neutralS = 1=2 particle. This is clearly related to the spinon excitation of Section IIIB 2; this is our nalcon mation of the intim ate connection between the non-collinear magnetic states of Section IIIA 2 and the topologically ordered states of Section IIIB 2.

This is a good point to mention, in passing, recent neutron scattering evidence for a RVB state in  $C s_2 C u C l_4$ (Coldea et al., 2001); the measurements also show noncollinear spin correlations, consistent with the connections being drawn here.

# N.ORDER N STATES PROXMATE TO MOTT NSULATORS

We are now ready to discuss the central issue of order parameters characterizing the cuprate superconductors. These superconductors are obtained by introducing mobile charge carriers into the M ott insulator of the square lattice of Cu ions that was discussed at the beginning of Section III. The charge carriers are introduced by substitutional doping. For instance, in the compound  $La_2 \quad Sr CuO_4$ , each trivalent  $La^{3+}$  ion replaced by a divalent  $Sr^{2+}$  ion causes one hole to appear in the M ott insulator of Cu ions: the concentration of these holes is per square lattice site.

For large enough , theory and experiment both indicate that such a doped M ott insulator is a d-wave superconductor characterized by the pairing am plitude (2). The reader can gain an intuitive (but quite crude and incomplete) understanding of this by the sim ilarity between the real-space, short-range pair in (9) and the m om entum -space, long-range pairing in (2). The undoped M ott insulator already has electrons paired into singlet valence bonds, as in (9), but the repulsive C oulom b energy of the M ott insulator prevents m otion of the charge associated with this pair of electrons. It should be clear from our discussion in Section IIIB that this singlet pairing is complete in the param agnetic M ott insulators, but we can also expect a partial pairing in the m agnetically ordered states. Upon introducing holes into the M ott insulator, it becomes possible to m ove charges around w ithout any additional C oulom b energy cost, and so the static valence bond pairs in (9) transm ute into the m obile C ooper pairs in (2); the condensation of these pairs leads to superconductivity. Note that this discussion is concerned with the nature of the ground state wavefunction, and we are not im plying a \m echanism " for the form ation of C ooper pairs.

The discussion in the previous sections has laid the groundwork for a more precise characterization of this superconductor using the correlations of various order param eters, and of their interplay with each other. The proxim ity of the M ott insulator indicates that the C ooper pairs should be considered descendants of the real-space, short range pairs in (9), and this clearly dem ands that all the magnetic, bond and topological order parameters discussed in Section III remain viable candidates for the doped M ott insulator. The m otion of charge carriers allows for additional order param eters, and the most im portant of these is clearly the superconducting order of the BCS state noted below (2) in Section II. In principle, it is also possible to obtain new order parameters which are characteristic of neither the BCS state nor a M ott insulator, but we such order param eters shall not be discussed here (discussions of one such order m ay be found in H su et al. (1991), W en and Lee (1996), Lee and Sha (2003), Chakravarty et al. (2001), and Schollwock et al. (2003)).

The arsenal of order param eters associated with M ott insulators and the BCS state permits a very wide variety of possible phases of doped M ott insulators, and of quantum phase transitions between them. Further progress requires experimental guidance, but we claim that valuable input is also obtained from the theoretical connections sketched in Section IIIC.

The simplest line of reasoning (Sachdev and Read, 1991) uses the fact that the undoped M ott insulator La<sub>2</sub>CuO<sub>4</sub> has collinear magnetic order as sketched in Fig 3a. The arguments above and those in Section III.C then imply that the doped Mott insulator should be characterized by the collinear magnetic order of Section IIIA 1, the bond order of Section IIIB 1, along with the phase order of BCS theory. This still perm its a large variety of phase diagram s, and some of these were explored in Sachdev and Read (1991), Vota and Sachdev (1999), Vojta et al. (2000a), and Vojta (2002), with detailed results on the evolution of bond order and superconductivity with increasing doping. However, this reasoning excludes phases associated with the non-collinear m agnetic order of Section IIIA 2 and the topological order of Section IIIB 2.

Som e support for this line of reasoning cam e from the breakthrough experiments of Tranquada et al. (1995), Tranquada et al. (1996), and Tranquada et al. (1997) on  $La_{2 \ y}$  N d<sub>y</sub>Sr O<sub>4</sub> for hole concentrations near = 1=8: they observed static, collinear m agnetic order near the

wavevectors K = (3 = 4; ) shown in Figs 3b,c, which coexisted m icroscopically<sup>9</sup> with superconductivity form ost . They also observed modulations in the bond order  $Q_a(\mathbf{r}_i)$  (Eqn (10)) at the expected wavevector, 2K . The experim entalists interpreted their observations in terms of modulations of the site charge density proportional to  $Q_0(\mathbf{r}_i)$  but the existing data actually do not discrim inate between the di erent possible values of  $r_a$ . As we noted earlier in Section IIIB.1, the physical considerations of the present article suggest that the modulation m ay be stronger with  $r_a \in 0$ . (The existing data also cannot distinguish between the magnetic orders in Fig 3b (site-centered) and Fig 3c (bond-centered), or between the bond orders in Fig 6c (orthorhom bic sym m etry) and Fig 6d (tetragonal sym m etry).) W e also m ention here the di erent physical considerations in the early theoretical work of Zaanen and Gunnarsson (1989), Machida (1989), Schulz (1989), and Poilblanc and Rice (1989) which led to insulating states with collinear magnetic order with wavevector  $\mathbf{K} \in (;)$  driven by a large site-charge density modulation in the dom ain walls of holes.

The following subsections discuss a number of recent experiments which explore the interplay between the order parameters we have introduced here. We argue that all of these experiments support the proposal that the cuprate superconductors are characterized by interplay between the collinear magnetic order of Section IIIA 1, the bond order of Section IIIB 1 (these are connected as discussed in Section IIIC 1), and the superconducting order of BCS theory.

#### A. Tuning order by means of a magnetic eld

In Section I, we identied a valuable theoretical tool for the study of system s with multiple order parameters: use a coupling g to tune the relative weights of static or uctuating order parameter correlations in the ground state. Is such a coupling available experimentally ? O ne choice is the hole concentration, , and we can assume here that g increases monotonically with . However, is often di cult to vary continuously, and it may be that sampling the phase diagram along this one-dimensional axis may not reveal the full range of physically relevant behavior. A second tuning parameter will be clearly valuable; here we argue that, under suitable conditions, this is provided by a magnetic eld applied perpendicular to the two-dimensional layers.

C onsider the case where both phases in F ig 1 are superconducting; the phase with  $g < g_c$  then has co-existence of long-range order in superconductivity and a secondary order parameter. We also restrict attention to the case

<sup>&</sup>lt;sup>9</sup> The m icroscopic co-existence of m agnetic order and superconductivity is not universally accepted, but strong arguments in its favor have been m ade recently by K haykovich et al. (2002).

where the transition at  $g = g_c$  is second order (related results apply also to rst order transitions, but we do not discuss them here). Imposing a magnetic eld, H, on these states will induce an inhom ogeneous state, consisting of a lattice of vortices surrounded by halos of super ow (we assume here that  $H > H_{cl}$ , the lower critical eld for ux penetration). In principle, we now need to study the secondary order parameter in this inhom ogenous background, which can be a problem of som e com plexity. However, it was argued by Dem ler et al. (2001) and Zhang et al. (2002) that the problem simpli es considerably near the phase boundary at  $q = q_c$ . Because of the diverging correlation length associated with the secondary order parameter, we need only look at the spatially-averaged energy associated with the relevant order param eters.<sup>10</sup> W e know from the standard theory of the vortex lattice in a BCS superconductor (Parks, 1969) that the energy density of the superconducting order increases by the fraction  $(H = H_{c2}) \ln (H_{c2} = H),$  $H_{c1}$  is the upper critical eld above which where H<sub>c2</sub> superconductivity is destroyed. Let us make the simple assumption that this change in energy of the superconducting order can also be characterized by a change in the coupling constant g. W e can therefore introduce an e ective coupling ge (H) given by

$$g_{e}$$
 (H) =  $g$   $C^{0}$   $\frac{H}{H_{c2}}$  ln  $\frac{H_{c2}}{H}$  (12)

where  $C^0$  is some constant of order unity. As g is linearly related to  $\ ,$  we can also rewrite this expression in terms of an elective doping concentration  $_{\rm e}$  (H ),

$$_{e}$$
 (H) = C  $\frac{H}{H_{c2}}$  ln  $\frac{H_{c2}}{H}$  ; (13)

where C is some other constant. These expressions in ply that we tune through di erent values of g or sim ply by varying the applied magnetic eld.

The sign of C is of som e physical in portance, and can be deduced by a simple argument. It is observed that in the lightly doped cuprates, decreasing leads to a stabilization of an order associated with the M ott insulator at the expense of the superconducting order. (There is a non-monotonic dependence on from commensurability e ects near = 1=8, but here too the magnetic order is stabilized at the expense of superconductivity). As increasing H clearly suppresses the superconducting order, it must be the case that  $_{\rm e}$  (H) decreases with increasing H. This implies that C > 0, and indicates a competition (Tranquada et al., 1997) between the two ground states, or order parameters, on either side of the quantum criticalpoint (Chubukov et al., 1994a; Sachdev, 2000; Zhang, 1997).

FIG.12 Phase diagram in the g;H plane deduced from (12). The phase boundary is determ ined by setting  $g_e$  (H) =  $g_c$ , which leads to a phase boundary at a critical eld H (g  $g_c$ ) = ln (l=(g  $g_c$ )). We assume that g is a monotonically increasing function of . The collinear magnetic order of F igs 3b and c is the secondary order parameter investigated in recent neutron scattering experiments in doped La<sub>2</sub>C uO<sub>4</sub>: the observations of Lake et al. (2001) are along the arrow A, and those of K atano et al. (2000), Lake et al. (2002), K haykovich et al. (2002), and K haykovich et al. (2002) are along the arrow B. The STM experiments of H o m an et al. (2002a), H o m an et al. (2002b), H ow ald et al. (2002), H ow ald et al. (2003) are along arrow C, and will be discussed in Section IV D.

The relationships (12) and (13) can be combined with F ig 1 to produce a phase diagram in the (g;H) (or (;H)) plane. This is shown in F ig 12. Notice that the phase boundary comes into the  $g = g_c$ , H = 0 point with vanishing slope. This implies that a relatively small eld is needed in the  $g > g_c$  region to tune a BCS superconductor across a quantum phase transition into a state with long-range correlations in the secondary order parameter. There are also some interesting modi cations to F ig 12 in the fully three-dimensionalm odel which accounts for the coupling between adjacent CuO<sub>2</sub> layers; these are discussed by K ivelson et al. (2002b).

A number of neutron scattering studies of the physics of Fig 12 in doped La<sub>2</sub>CuO<sub>4</sub> have recently appeared. The secondary order param eter here is the collinearm agnetic order of Figs 3b and c, which is also observed in  $La_2 v$  Nd<sub>v</sub>SrO<sub>4</sub> as discussed above. Earlier, a series of beautiful experim ents by W akim oto et al. (1999), Lee et al. (1999), and W akim oto et al. (2001) established that La<sub>2</sub> Sr CuO<sub>4</sub> has long-range, collinear m agnetic order co-existing with superconductivity for a range of values above = 0:055. M oreover, the anom alous frequency and tem perature dependence of the dynam ic spin structure factor (Chubukov et al, 1994a; Sachdev and Ye, 1992) in neutron scattering experiments by A eppliet al. (1997) gave strong indications of a second-order quantum phase transition near 0:14 at which the magnetic order vanished. W e identify this transition with the point  $q = q_{c}$ , H = 0 in Fig 12. Recent studies have explored the region with H > 0: Lake et al. (2001) observed a softening of a collective spin excitation mode at = 0.163 in the presence of an applied magnetic eld. W e interpret this as a consequence of the low H approach to the phase boundary in Fig 12 in the  $q > q_c$  region, as indicated by the arrow labeled A. Notice that the eld was not large

<sup>&</sup>lt;sup>10</sup> Evidence that the primary e ect of a magnetic eld is a spatially uniform modi cation of the magnetic order has appeared in recent muon spin resonance experiments (Sonier et al., 2003; U em ura, 2003).

enough to cross the phase boundary.

A separate set of experiments have examined the H dependence of the static magnetic moment in the superconductor with  $g < g_c$  in La<sub>2</sub> Sr CuO<sub>4</sub> (K atano et al., 2000; Lake et al., 2002) and La<sub>2</sub>CuO<sub>4+y</sub> (K haykovich et al., 2003, 2002), along the arrow indicated by B in F ig 12. The theoretical prediction (D em ler et al., 2001; Zhang et al., 2002) for these experiments is a simple consequence of (12) and (13). Let I (H; ) be the observed intensity of the static magnetic moment associated with the order in Figs 3b, c at a eld H and doping . If we assume that the dom inant e ect of the eld can be absorbed by replacing by the eld can be conserved with the order of the static magnetic moment associated with the order of the dom inant eld H and doping and the absorbed by replacing by the eld can be absorbed by replace by the eld can be absorbed by the eld can be absorbed

I(H;) I(H = 0; (H))  
I(H = 0; ) + D 
$$\frac{H}{H_{c2}}$$
 ln  $\frac{H_{c2}}{H}$ ; (14)

where in the second expression we have used (13) and expanded in powers of the second argument of I. Reasoning as in the text below (13) for C, we use the experimental fact that a decrease in leads to an increase in the magnetic order, and hence D > 0. The results of recent experiments (K haykovich et al., 2003, 2002; Lake et al., 2002) are in good agreement with the prediction (14), with a reasonable value for D obtained by tting (14) to the experimental data.

### B. Detecting topological order

The magnetic and bond orders break simple symmetries of the H am iltonian, and, at least in principle, these can be detected by measurement of the appropriate two-point correlation function in a scattering experiment. The topological order of Sections IIIB 2 and IIIC 2 is a farm ore subtle characterization of the electron wavefunction, and can only be observed indirectly through its consequences for the low energy excitations. We review here the rationale behind some recent experimental searches (B onn et al., 2001; W ynn et al., 2001) for topological order.

The searches relied on a peculiar property of a superconductor proxim ate to a M ott insulator with topological order: there is a fundam ental distinction in the internal structure of vortices in the superconducting order, speci ed by (3), which depends on whether the integer  $n_v$  is even or odd. This di erence was noted (Nagaosa and Lee, 1992; Sachdev, 1992) in the context of a simple meaneld theory of a superconductor near an insulating spin gap state. However, the signi cance and interpretation of the mean-eld result, and in particular its connection with topological order, did not become apparent until the far-reaching work of Senthil and Fisher (2000), Senthil and Fisher (2001a), and Senthiland Fisher (2001b). The arguments behind the dependence on the parity of  $n_v$ are subtle, and only an outline will be sketched here the reader is referred to Senthil and Fisher (2001a) and

Senthiland F isher (2001b) for a complete exposition. A lthough the superconducting order of BCS theory in (2) and the topological order of the M ott insulator are quite distinct entities, there is an important connection between them in the superconducting state: each vortex with  $n_v$  odd in (3) has a vison attached to it. The vison gap in the proximate M ott insulator then increases the energy required to create  $n_v$  odd vortices, while this extra energy is not required for  $n_v$  even.

The connection between  $n_v$  odd vortices and visons is m ost transparent for the case where the spinons in the M ott insulator obey ferm ionic statistics. We considered bosonic spinons z in Section III.C 2, but they can transm ute into ferm ionsby binding with a vison (D em leretal., 2002; K ivelson, 1989; Read and Chakraborty, 1989): we represent the ferm ionic spinon by  $f_j$ . In the doped M ott insulator, each electron annihilation operator,  $c_j$ , m ust create at least one neutral S = 1=2 spinon excitation, along with a charge e hole (K ivelson et al., 1987), and we can represent this schem atically by the operator relation

$$c_j = b_j^{\mathrm{V}} f_j ; \qquad (15)$$

where  $b_j^{y}$  creates a bosonic spinless hole. In this picture of the doped M ott insulator, the presence of superconductivity as in (2) requires both the condensation of the  $b_j$ , along with the condensation of  $\C$  ooper pairs" of the spinons  $f_j$ . We can deduce this relationship from (2) and (15) which im ply, schem atically

$$_{0} = _{f} b^{2};$$
 (16)

where we have ignored spatial dependence associated with the internal wavefunction of the Cooper pair (hence there are no site subscripts j in (16)), and fh£<sub>i"</sub>f<sub>i⁰#</sub>i is the spinon pairing am plitude. From (16) we see if the phase of b; winds by 2 upon encircling som e defect site, then phase of  $_0$  will wind by 4, and this corresponds to a vortex in the superconducting order with  $n_v = 2$ in (3). Indeed, the only way (16) can lead to an elem entary vortex with  $n_v = 1$  is if the phase of the spinon pair am plitude, f, winds by 2 upon encircling the vortex: the latter is another description of a vison (Senthil and Fisher, 2000). This argument is easily extended to show that every odd  $n_v$  vortex must be associated with at least an elementary vortex in the phase of f, thus establishing our claim ed connection.

Su ciently close to the M ott insulator, and near a second-order superconductor-insulator transition, the energy required to create a vison raises the energy of  $n_v = 1$  vortices, and the lowest energy vortex lattice state in an applied magnetic eld turns out to have vortices with ux hc=e, which is twice the elementary ux (Sachdev, 1992). This should be easily detectable, but such searches have not been successful so far (W ynn et al., 2001).

M ore recently Senthil and Fisher (2001a) have proposed an ingenious test for the presence of visons, also relying on the binding of a vison to a vortex with uc hc=(2e). Begin with a superconductor in a toroidal geom – etry with ux hc=(2e) penetrating the hole of the torus. By the arguments above, a vison is also trapped in the hole of the torus. Now by changing either the temperature or the doping level of the superconductor, drive it into a normal state. This will allow the magnetic ux to escape, but the topological order in the bulk will continue to trap the vison. Finally, return the system back to its superconducting state, and, quite remarkably, the vison will cause the magnetic ux to reappear. An experimental test for this \ ux memory e ect" has also been undertaken (Bonn et al., 2001), but no such e ect has yet been found.

So despite som e innovative and valuable experimental tests, no topological order has been detected so far in the cuprate superconductors.

## C. Non magnetic impurities

We noted in Section IIIB.1 that one of the key consequences of the con nement of spinons in the bondordered param agnet was that each non-magnetic in purity would bind a free S = 1=2 m om ent. In contrast, in the topologically ordered RVB states of Section IIIB 2, such a m om ent is not generically expected, and it is m ore likely that the \liquid" of valence bonds would readjust itself to screen away the o ending in purity without releasing any free spins.

M oving to the doped M ott insulator, we then expect no free S = 1=2 m om ent for the topologically ordered case. The remaining discussion here is for the con ning case; in this situation the S = 1=2 m om ent m ay well survive over a nite range of doping, beyond that required for the onset of superconductivity. Eventually, at large enough hole concentrations, the low energy ferm ionic excitations in the d-wave superconductor will screen the moment (by the Kondo e ect) at the lowest tem peratures. How ever, unlike the case of a Ferm i liquid, the linearly vanishing density of ferm ionic states at the Ferm i level in plies that the K ondo tem perature can be strictly zero for a nite range of parameters (Gonzalez-Buxton and Ingersent, 1998; Vota and Bulla, 2002; W tho and Fradkin, 1990). So we expect each non-m agnetic im purity to create a free S = 1=2 m om ent that survives dow n to T = 0 for a nite range of doping in a d-wave superconductor proximate to a con ning M ott insulator. The collinear magnetic or bond order in the latter insulator m ay also survive into the superconducting state, but there is no fundam ental reason for the disappearance of these long-range orders (bulk quantum phase transitions) to coincide with the zero temperature quenching of the moment (an impurity quantum phase transition).

A very large number of experimental studies of nonmagnetic Zn and Li impurities have been carried out. Early on, in electron paramagnetic resonance experiments Finkelstein et al. (1990) observed the trapping of an S = 1=2 moment near a Zn impurity above the superconducting critical temperature, and also noted the implication of their observations for the connement of spinons, in the spirit of our discussion above. Subsequent speci cheat and nuclearm agnetic resonance experiments (A lloul et al., 1991; B obro et al., 2001; Julien et al., 2000; Sisson et al., 2000) have also explored low temperatures in the superconducting state, and not evidence of spin moments, which are eventually quenched by the K ondo e ect in the large doping regime. Especially notable is the recent nuclear magnetic resonance evidence (B obro et al., 2001) for a transition from a T = 0 free

We interpret these results as strong evidence for the presence of an S = 1=2 m om ent near non-m agnetic im - purities in the lightly doped cuprates. We have also argued here, and elsewhere (Sachdev and Vojta, 2000), that the physics of this m om ent form ation is m ost naturally understood in term s of the physics of a proxim ate M ott insulator with spinon con nem ent.

m om ent state at low doping, to a K ondo quenched state

at high doping.

The creation of a free m agnetic m om ent (w ith a local m agnetic susceptibility which diverges as 1=T as  $T \cdot 0$ ) near a single in purity in plies that the cuprate superconductors are exceptionally sensitive to disorder. O ther defects, such as vacancies, dislocations, and grain boundaries, which are invariably present even in the best crystals, should also have sim ilar strong e ects. W e speculate that it is this tendency to produce free m om ents (and local spin order which w illbe induced in their vicinity) which is responsible for the frequent recent observation of m agnetic m om ents in the lightly doped cuprates (Sidis et al., 2001; Sonier et al., 2001).

#### D. STM studies of the vortex lattice

Section IV A discussed the tuning of collinear magnetic order by means of an applied magnetic eld, and its detection in neutron scattering experiments in doped La<sub>2</sub>CuO<sub>4</sub>. This naturally raises the question of whether it may also be possible to detect the bond order of Section IIIB.1 som ewhere in the phase diagram of Fig 12. C learly the state with co-existing collinearm agnetic and superconducting order (explored by experim ents along the arrow B) should, by the argum ents of Section III.C. 1, also have co-existing bond order. However, more interesting is the possibility that the BCS superconductor itself has local regions of bond order for H  $\pm$  0 (Park and Sachdev, 2001). As we have argued, increasing H increases the weight of the M ott insulator order param eter correlations in the superconducting ground state. The appearance of static m agnetic order requires breaking of spin rotation invariance (in the plane perpendicular to the applied eld), and this cannot happen until there is a bulk phase transition indicated by the phase boundary in Fig 12. In contrast, bond order only breaks translational sym m etry, but this is already broken by the vortex lattice induced by a non-zero H . The sm all vortex

cores can pin the translational degree of freedom of the bond order, and a halo of static bond order should appear around each vortex core (D em ler et al., 2001; Park and Sachdev, 2001; Polkovnikov et al., 2002a, b; Zhang et al., 2002). Notice that this bond order has appeared in the state which has only superconducting order at H = 0, and so should be visible along the arrow labelled C in Fig 12. Recall also our discussion in Section IIIB.1 that site charge order is a special case of bond order (with  $r_a = 0$  in the bond order parameter  $Q_a(r)$ ).

Many other proposals have also been made for additional order parameters within the vortex core. The earliest of these involved dynamic antiferrom agnetism (Nagaosa and Lee, 1992; Sachdev, 1992), and were discussed in Section IV B in the context of topological order. O thers (Andersen et al., 2003; A rovas et al., 1997; Chen et al., 2002; Chen and Ting, 2002; Franz et al., 2002; Ghosal et al., 2002; Ichioka and Machida, 2002; Zhang, 1997; Zhu et al., 2002) involve static magnetism within each vortex core in the superconductor.<sup>11</sup> This appears unlikely from the perspective of the physics of F ig 12, in which static magnetism only appears after there is a cooperative bulk transition to long-range magnetic order, in the region above the phase boundary; below the phase boundary there are no static \spins in vortices," but there is bond order as discussed above (Park and Sachdev, 2001; Zhang et al., 2002). (Static spins do appear in the three space dimensional model with spin anisotropy and inter-planar couplings considered in K ivelson et al. (2002b).) A separate proposal involving staggered current loops in the vortex core (K ishine et al., 2001; Lee and Sha, 2003; Lee and W en, 2001) has also been m ade.

Nanoscale studies looking for signals of bond order along the arrow C in Fig 12 would clearly be helpful. Scanning tunnelling m icroscopy (STM ) is the ideal tool, but requires atom ically clean surfaces of the cuprate crystal. The detection of collinear magnetic order in doped La2CuO4 makes such materials ideal candidates for bond order, but they have not been am enable to STM studies so far. Crystals of Bi<sub>2</sub>Sr<sub>2</sub>CaCu<sub>2</sub>O<sub>8+</sub> have been the focus of num erous STM studies, but there is little indication of magnetic order in neutron scattering studies of this superconductor. Nevertheless, by the reasoning in Fig 12, and using the reasonable hypothesis that a comm on picture of competing superconducting, bond, and collinear magnetic order applies to all the cuprates, it is plausible that static bond order should appear in  $B_{1_2}Sr_2CaCu_2O_{8+}$  for large enough H along the arrow C in Fig 12.

A number of atomic resolution STM studies of  $B_{12}Sr_2CaCu_2O_{8+}$  surfaces have appeared recently (Ho - m an et al., 2002a,b; Howald et al., 2003, 2002). Ho m an et al. (2002a) observed a clear signal of m odulations in

the local density of electronic states, with a period of 4 lattice spacings, in a halo around each vortex core. There was no corresponding m odulation in the surface topography, in plying there is little modulation in the charge density. However, a bond order modulation, such as those in Figs 6c and d, could naturally lead to the required modulation in the local density of states. O ther studies (Ho man et al, 2002b; Howald et al, 2003, 2002) have focused on the H = 0 region: here the modulations appear to have signi cant contributions (Byers et al, 1993; W ang and Lee, 2003) from scattering of the ferm ionic S = 1=2 quasiparticles of the superconductor (Section II), but there are also signals (Howald et al., 2003, 2002) of a weak residual periodic modulation in the density of states, similar to those found at H  $\pm$  0. Theoretically (Howald et al., 2003; Kivelson et al., 2002a; Polkovnikov et al., 2003), it is quite natural that these quasiparticle and order param eter m odulations co-exist. Howald et al. (2002) and Howald et al. (2003) also presented results for the energy dependence of this periodic modulation, and these appear to be best modelled by m odulations in m icroscopic bond, rather than site, variables (Podolsky et al., 2003; Vota, 2002; Zhang, 2002).

This is a rapidly evolving eld of investigation, and future experiments should help settle the interpretation of the density of states modulations both at H = 0 and  $H \neq 0$ . It should be noted that because translational symmetry is broken by the vortices or the pinning centers, there is no fundamental symmetry distinction between the quasiparticle and the pinned-uctuating-order contributions; nevertheless, their separate spectral and spatial features should allow us to distinguish them.

## V. A PHASE DIAGRAM W ITH COLLINEAR SPINS, BOND ORDER, AND SUPERCONDUCTIVITY

W e have already discussed two experim ental possibilities for the coupling g in Fig 1, which we used to tune the ground state of the doped M ott insulator between various distinct phases: the doping concentration, , and the strength of a magnetic eld, H, applied perpendicular to the layers. A simple phase diagram in the sm all H region as a function of these param eters was presented in Fig 12, and its implications were compared with a num ber of experiments in Sections IV A and IV D. However, even though it is experimentally accessible, the eld H induces a large scale spatial modulation associated with the vortex lattice, and is consequently an inconvenient choice for m icroscopic theoretical calculations. Here we follow the strategy of introducing a third theoretical axis, which we denote schem atically by g, to obtain a global view of the phase diagram . As we argue below, information on the phases present as a function of g sheds considerable light on the physics as a function of H .

The crucial role of order parameters characterizing M ott insulators in our discussion suggests that we should work with a coupling, **g**, which allows exploration of

<sup>&</sup>lt;sup>11</sup> A lso, Ichioka et al. (2001) studied the vortex lattice in a state with pre-existing long-range collinear spin order

di erent ground states of M ott insulators already at

= 0. The range of this coupling should obviously include regim es where the M ott insulator has the m agnetically ordered ground state of F ig 3a, found in  $La_2CuO_4$ . Now imagine adding further neighbor couplings in (5) which frustrate this magnetic order, and eventually lead to a phase transition to a paramagnetic state.<sup>12</sup> As discussed in Section III.C.1, it was argued (Read and Sachdev, 1989b, 1990; Sachdev and Park, 2002) that any param agnetic state so obtained should have bond order, m ost likely in the patterns in Figs 6a and b.

It would clearly be useful to have num erical studies which tune a coupling g acting in the manner described above. Large scale computer studies of this type have only appeared recently. The rst results on a quantum antiferrom agnet which has a spin of S = 1=2 per unit cell, whose Ham iltonian maintains full square lattice symmetry, and in which it is possible to tune a coupling to destroy the collinear magnetic order, were obtained recently by Sandvik et al. (2002). Their model extended (5) with a plaquette ring-exchange term, and had only a U (1) spin rotation symmetry. Theoretical extensions to this case have also been discussed (Lannert et al., 2001; Park and Sachdev, 2002). A long with the collinear magnetic state in the small ring-exchange region (small g), Sandvik et al. (2002) found the bond-ordered param agnetic state of Fig 6a in the large ring-exchange region (large g).

A second large scale com puter study of the destruction of collinear m agnetic order on a m odel with S = 1=2 per unit cell was perform ed recently by H arada et al. (2003). They generalized the spin sym m etry group from SU (2) to SU (N); in our language, they used the value of N as an e ective g. They also found the bond order of F ig 6a in the param agnetic region.

These theoretical studies give us condence in the theoretical phase diagram as a function of **g** and sketched in Fig 13 (Sachdev and Read, 1991; Vojta, 2002; Vojta and Sachdev, 1999; Vojta et al., 2000a). Phase diagram s with related physical ingredients, but with signi cant differences, appear in the work of K ivelson et al. (1998) and Zaanen (1999).

In portant input in sketching F ig 13 was provided by theoretical studies of the e ects of doping the bondordered param agnetic M ott insulator at large g. In this region without m agnetic order, it was argued that a system atic and controlled study of the doped system was provided by a generalization of the SU (2) spin symmetry<sup>13</sup> to Sp (2N ), followed by an expansion in 1=N. This

FIG.13 Zero tem perature, zero m agnetic eld phase diagram as a function of the doping  $\$  , and a coupling constant  $\mathbf{g}$ . Here **g** is, in principle, any coupling which can destroy the collinear m agnetic order at (;) in the undoped insulator, while the Ham iltonian maintains full square lattice symmetry with spin S = 1=2 per unit cell. The states are labeled by the orders which exhibit long-range correlations: collinear magnetic (CM), bond (B) and d-wave-like superconductivity (SC).At = 0, the CM order is as in Fig 3a, the B order is as in Fig 6a or b, and we have assumed a co-existing CM + Bregion, following Sachdev and Park (2002) and Sushkov et al. (2001). The ground state will rem ain an insulator for a sm all range of > 0 (induced by the long-range Coulom b interactions), and this is represented by the shaded region. The CM order for > 0 could be as in Fig 3b or c, and the B order as in Figs 6a, b, c, or d, but a variety of other periods are also possible (Vota, 2002; Vota and Sachdev, 1999). The dashed line indicates the path followed in Fig 12 at H = 0, but the physical situation could also lie along line . A number of other complex phases are possible in the vicinity of the multicritical point M ; these are not shown but are discussed in Zhang et al. (2002), Zaanen et al. (2001), and Zaanen and Nussinov (2003) and also, brie y, in Section VI.

approach directly gives (Sachdev and Read, 1991) a stable bond-ordered state at = 0, a stable d-wave superconductor at large , and a region in which these two orders co-exist at sm all values of ; all of these phases are nicely in accord with the overallphilosophy of the present article. This analysis of a model with purely short-range interactions also found a phase separation instability at sm allvalues of (Sachdev and Read, 1991), whose in portance had been em phasized by others (B ang et al., 1991; Em ery et al., 1990) on di erent grounds. With longrange C oulom b interactions no m acroscopic phase separation is possible, and we have to deal with the physics of frustrated phase separation (Em ery et al., 1990). The interplay between bond order and d-wave superconduc-

<sup>&</sup>lt;sup>12</sup> W e assume that there is no interm ediate state with non-collinear m agnetic order, as this is not supported by observations so far.

<sup>&</sup>lt;sup>13</sup> The group SU (2) is identical to the sym plectic group Sp (2), but the group SU (2N) is distinct from Sp (2N) for N > 1. Consequently, distinct 1=N expansions are generated by models with SU (2N) or Sp (2N) sym metry. The Sp (2N) choice better captures the physics discussed in this article, for reasons explained

in Sachdev and Read (1991)

tivity has been studied in som e detail in this region (Voja, 2002; Vo ja and Sachdev, 1999; Vo ja et al., 2000a): m ore com plex bond ordered structures with large periods can appear, usually co-existing with superconductivity (as sketched in Fig 13). Predictions were m ade for the evolution of the ordering wavevector with , and the period 4 structures in Figs 6c and d were found to be especially stable over a wide regime of doping and param eter space.

The phase diagram of Fig 13 also includes a region at small g, with collinear magnetic order, which is not directly covered by the above computations. \Stripe physics" (Machida, 1989; Poilblanc and Rice, 1989; Schulz, 1989; Zaanen and Gunnarsson, 1989) the accumulation of holes on sites which are anti-phase domain walls between Neel ordered regions is associated with this region. How ever, these stripe analyses treat the magnetic order in a static, classical manner, and this misses the physics of valence bond form ation that has been em phasized in our discussion here. A related feature is that their dom ain walls are fully populated with holes and are insulating. Upon including quantum uctuations accounting for valence bonds, it appears likely to us that the stripes will have partial lling (K ivelson and Em ery, 1996; Nayak and Wilczek, 1997), acquire bond order, and co-exist with superconductivity, as has been assumed in our phase diagram in Fig 13. Indeed, as we have em phasized throughout, it may well be that the modulation in the site charge density which is proportional to  $Q_a(\mathbf{r})$ with  $r_a = 0$  in (10) is quite small, and most of the modulation is for  $r_a \in 0$ .

The reader should now be able to use the perspective of the phase diagram in Fig 13 to illum inate our discussion of experim ents in Section IV. The phase diagram in F ig 12, used to analyze neutron scattering experim ents in Section IV A and STM experiments in Section IV D, has its horizontal axis along the line labeled in Fig 13; the phases that appear in Fig 12 as a function of increasing H should be related to those in Fig 13 as a function of increasing g, although the detailed location of the phase boundaries is surely di erent.<sup>14</sup> The absence of topologicalorder in the experim ents discussed in Section IV B, is seen in Fig 13 to be related to the absence of states with non-collinear spin correlations or topological order. The form ation of S = 1=2 m om ents near non-m agnetic in purities is understood by the proxim ity of con ning, bondordered phases in Fig 13. The possible signals of bond order in a superconductor at H = 0 in the STM observations of Howald et al. (Howald et al., 2003, 2002), may be related to the B + SC phase along the line in Fig 13; similarly, the observations of Homan et al. (Homan et al, 2002a) at H 6 0 can be interpreted by the prox-

 $^{14}$  M ore precisely, generalizing the arguments leading to (12) and (13), we can state that the system is characterized by an elective  ${\bf g}$  which increases linearly with H ln(1=H), and an elective which decreases linearly with H ln(1=H)

im ity of the B + SC phase at H = 0.

## VI. OUTLOOK

The main contention of this article is that cuprate superconductors are best understood in the context of a phase diagram containing states characterized by the pairing order of BCS theory, along with orders associated with M ott insulators; the evidence so far supports the class of M ott insulators with collinear spins and bond order. The interplay of these orders perm its a rich variety of distinct phases, and the quantum critical points between them o er fertile ground for developing a controlled theory for interm ediate regim es characterized by multiple competing orders. This approach has been used to analyze and predict the results of a num ber of recent neutron scattering, uxoid detection, NMR, and STM experim ents, as we have discussed in Sections IV A, IV B,  $\operatorname{IV}\nolimits {\mathcal L}$  , and  $\operatorname{IV}\nolimits {D}$  . Further experim ental tests have also been proposed, and there are bright prospects for a m ore detailed, and ultimately quantitative, confrontation between theory and experiment.

All of the experimental comparisons here have been restricted to very low temperatures. The theory of crossovers near quantum critical points also implies interesting anom alous dynamic properties at nite temperature (Sachdev, 1999; Sachdev and Ye, 1992), but these have not been discussed. However, we did note in Section IV A that the transition involving loss of magnetic order in a background of superconductivity was a natural candidate for explaining the singular temperature and frequency dependence observed in the neutron scattering at 0:14. (A eppliet al., 1997)

There have also been several recent experim ental proposals for a quantum critical point in the cuprates at

0:19, linked to anom alous quasiparticle damping (Valla et al., 1999), therm odynamic (Tallon and Loram, 2001), or magnetic (Panagopoulos et al., 2003, 2002) properties. The study of Panagopoulous and collaborators presents evidence for a spin glass state below the critical doping, and this is expected in the presence of disorder at dopings lower than that of the point M in Fig 13.

A m ong theoretical proposals, a candidate for a quantum critical point (Sachdev and M orinari, 2002; Zaanen et al., 2001; Zhang et al., 2002) at large dopings is a novel topological transition which can occur even in systems s with collinear spin correlations. W hile the topological order present in systems with non-collinear spin correlation leads to fractionalization of the electron (as discussed in Section IV B), the collinear spin case exhibits a very di erent and much less disruptive transition in which the electron retains its integrity, but the spin and charge collectivem odes fractionalize into independent entities. Note that this fractionalization transition was not explicitly shown in F ig 13, and is associated with an additional interm ediate state which m ay appear near the point M . O ther theoretical proposals for quantum critical points are linked to the bond/charge order (K ivelson et al., 1998; Seibold et al., 1998) in Fig 13, to order associated with circulating current loops (Chakravarty et al., 2001; Varma, 1997) which has not been discussed in this paper, and to a tim e-reversal symmetry breaking transition (K hveshchenko and Paaske, 2001; Laughlin, 1998; Sangiovanni et al, 2001; Vota et al, 2000b) between  $d_{x^2 y^2}$  and  $d_{x^2 y^2} + id_{xy}$  superconductors. This last proposal o ers a possible explanation of the quasiparticle dam ping m easurem ents (Valla et al., 1999). Note that this transition does not involve any order associated with the M ott insulator. Indeed, the  $d_{x^2 y^2} + id_{xy}$  order can be understood entirely within the fram ework of BCS theory, and experimental support for  $d_{x^2 y^2} + id_{xy}$  superconductivity in recent tunnelling experiments (D agan and Deutscher, 2001) appears in the overdoped regime, wellaway from the Mott insulator.

#### A cknow ledgm ents

I have bene ted from discussions and collaborations with many physicists: here I would like to especially thank Gabriel Aeppli, Henri Alloul, Robert Birgeneau, Andrey Chubukov, Seam us Davis, Eugene Dem ler, Matthew Fisher, Aharon Kapitulnik, Steve Kivelson, Christos Panagopoulos, Kwon Park, Anatoli Polkovnikov, T. Senthil, Matthias Vojta, Jan Zaanen, and Ying Zhang for valuable interactions in recent years. This article is based on the F.A.Matsen Endowed Regents Lecture on the Theories of Matter at the University of Texas at Austin, O ctober 2002. This research was supported by US NSF G rant DMR 0098226.
