Phase phonon spectrum and melting in a quantum rotor model with diagonal disorder

W . A . A l-Saidi and D . Stroud^y

Department of Physics, The Ohio State University, Columbus, Ohio 43210

(D ated: M arch 22, 2024)

W e study the zero-tem perature (T = 0) quantum rotorm odelw ith on-site disorder in the charging energy. Such a model may serve as an idealized H am iltonian for an array of Josephson-coupled sm all superconducting grains, or super uid ⁴H e in a disordered environment. In the approximation of sm all-am plitude phase uctuations, the H am iltonian maps onto a system of coupled harmonic oscillators with on-site disorder. W e study the e ects of disorder in this harmonic regime, using the coherent potential approximation (CPA), obtaining the density of states and the lifetimes of the spin-wave-like excitations for several choices of the parameters which characterize the disorder. Finally, we estimate the parameters characterizing the T = 0 quantum melting of the phase order, using a suitable Lindem ann criterion.

I. IN TRODUCTION

The quantum rotor model is a widely studied H am iltonian which may serve as an idealized representation of many physical systems. It consists of two parts: a potential energy which represents the coupling between two-component spin variables of xed length (an XY" H am iltonian) and the kinetic energy of those spins. The model is quantum -m echanical because the potential and kinetic energies do not commute.

One possible realization of this model is a Josephson junction array, i.e., a collection of superconducting islands with Josephson or proximity e ect tunneling between the islands. Such arrays can be produced experim entally in a wide range of geom etries, and with a great variety of individual junction parameters. They may be described by the quantum rotor model in the limit of small grains. In this case the potential energy corresponds to the Josephson coupling, and the kinetic energy corresponds to the charging energy. Such arrays can serve as model systems for studying quantum phase transitions¹ under conditions such that the experim ental param eters can be readily tuned.² Recently, it has also been proposed that Josephson junctions may serve as a quantum bit (qubit) in quantum information technology, where the quantum logic operations would be perform ed by controlling gate voltages or magnetic elds.

The quantum rotorm odelm ay also be realized in other physical systems. For example, in liquid ⁴He, the potential energy may represent a discretized form of the gradient energy term in the G inzburg-Landau free energy of super uid ⁴He, and favors a state in which all parts of the super uid have the same phase, while the kinetic energy term is the energy associated with the time-variation of the order parameter phase. The model may be particularly useful for helium Ims and helium in con ned geom etries such as porous glasses. The spectrum of elementary excitations in such con ned geom etries has recently been studied extensively.⁴ This spectrum may be treatable by the quantum rotorm odel.

In this paper, we study a special kind of quantum ro-

tor model, namely, the two-dimensional model with diagonal disorder in the kinetic energy. Our emphasis in this study is to understand what happens to the spectrum of elementary excitations in the presence of this disorder. W e also investigate the conditions for the destruction of phase order in this model arising from such quantum uctuations in the phase variables. This model includes a particularly simple form of disorder. In the case of a Josephson junction array (JJA), it would correspond to uctuations in the self-capacitance of individualgrains, but no signi cant random ness in the Josephson coupling between the superconducting grains. In the case of super uid helium, the diagonal disorder might correspond to random ness in the pore geometry (for a three-dimensional system) or arising from surface roughness (for a thin lm).

In the present paper, we are primarily interested in the spectrum of elementary excitations in this model at low tem peratures. We therefore adopt a simple meaneld approximation which has been successfully used to treat elem entary excitations in other system s. This is the coherent potential approximation (CPA), as described originally by Soven,⁵ Taylor et $al_{\ell}^{6,7}$ and Velicky et al_{\star}^{8} For the present problem, the CPA may be adequate at very low tem peratures, under conditions such that the original H am iltonian can be approxim ated as harm onic. At higher tem peratures, or under conditions such that the harm onic approximation is inadequate, it will be necessary to consider a more sophisticated approxim ation, such as the self-consistent harm onic approxim ation (SCHA),^{9,10,11} or a eld-theoretic treatment in which the charging energy is mapped onto a coupling in the imaginary time direction.¹²

The remainder of this paper is organized as follows. In the next section, we present the model H am iltonian, and its relation to a set of coupled harmonic oscillators. In Sec. III, we describe how the CPA may be used to study the disorder-averaged properties of the model H am iltonian in the harmonic approximation. Our numerical results based on the CPA are presented in Sec. IV, followed by a concluding discussion in Sec. V. W e will consider the following model H am iltonian:

$$H = \frac{1}{2} X U_{j} n_{j}^{2} + J_{jk} [1 \cos(j_{k})]: (1)$$

Here $_{j}$ is the phase of the quantum rotor, and n_{j} is a variable which is quantum -m echanically conjugate to the angle $_{j}$. n_{j} and $_{k}$ are assumed to have commutation relations

$$[h_j; k] = i_{jk}; \qquad (2)$$

where $_{jk}$ is a K ronecker delta function and [:::] represents a commutator. In Eq. (1), the rst sum runs over sites j, and the second sum runs over all distinct pairs of sites j and k. If this model is assumed to describe a Josephson junction array, then the rst term represents the capacitive energy of the array in the diagonal approximation. The most general form of this capacitive energy would be $\frac{1}{2}$ $_{jk} U_{jk} n_j n_k$; in Eq. (1), we make the approximation $U_{jk} = U_{j-jk}$, where U_j is related to the diagonal capacitance C_j, or alternatively to an elective $\mass" M_j$,

$$U_{j} = \frac{4e^{2}}{C_{j}} - \frac{h^{2}}{M_{j}}$$
: (3)

The second term represents the sum of the Josephson coupling energies between grains j and k. In Eq. (1), it is implicitly assumed that there is no contribution to H arising from dissipation. In this paper, we shall assume that $J_{ij} \in 0$ only if i and j are nearest-neighbor grains, and that, furtherm ore, there is no disorder in this nearest-neighbor coupling, i.e., that $J_{ij} = J$ for all nearest neighbor pairs i and j. Hereafter, we shall refer to this model H am iltonian as describing a Josephson junction array, although, as noted above, the model is also applicable, in principle, to other physical system s.

For su ciently low temperatures, we assume that the above H am iltonian can be approximated by its harm onic form :

$$H_{ham} = \frac{1}{2} \sum_{j}^{X} U_{j} n_{j}^{2} + \frac{1}{2} J_{hjki}^{X} (j_{k})^{2} K + V; (4)$$

where the second sum runs over distinct nearest neighbor pairs. W hile one can go beyond the harm onic approxim ation by using a self-consistent phase phonon approach,^{9,10} we shall here consider only the harm onic approxim ation, which is more easily combined with a treatment of disorder. The Heisenberg equation of motion of the phase variable is in $\neg = [j;H] = iU_jn_j$, where the last equality follows from the commutation relation (2). This equation m akes clear that H_{harm} is form ally analogous to an array of \m asses" M $_j$ harm onically coupled by springs of \spring constant" J. However, in contrast to a real lattice ofm asses and springs, there is no polarization degree of freedom . K and V represent the kinetic and potential energy term s in this H am iltonian. A disordered array of such oscillators can thus be treated by the sam e m ethods used to treat disordered arrays of coupled oscillators.

In this paper, we shall consider a bim odal distribution of the U_j 's. Thus we take $U_j = U_1$ or U_2 with probabilities p and 1 p respectively. W e also assume that the type 1 and type 2 grains are random ly distributed on an ideal lattice, with no correlation between the occupancies of neighboring sites. W ith this choice, the Ham iltonian (4) is analogous to the classic problem of substitutional mass disorder in phonon spectra, except that the \phase phonon" excitations have only one possible polarization. This problem has previously been studied by Soven,⁵ Taylor⁶, and E lliott and Taylor,⁷ using the coherent potential approximation.^{5,6,7,8} In the present paper, we shall use the same approach to study the e ects of disorder in the \phase phonon" spectrum . Note that because the entire H am iltonian is invariant under a global rotation of phases, the long-wavelength phase phonons are Goldstone bosons with frequencies that go to zero linearly in the wave vector k, even in the presence of disorder, and even in two dimensions.

III. COHERENT POTENTIAL APPROXIMATION

A. General equations

The CPA provides an approximate way of calculating the disorder-averaged G meen's function

G(z)
$$\frac{1}{z H_{harm}}$$
; (5)

where z is a complex variable, H $_{harm}$ is the H am iltonian operator, and h:::i_{dis} represent an average over disorder realizations. O fparticular interest is the diagonalm atrix element of this operator, which we write

$$F(z) = hjf_{G}(z)jj_{I} G(j;j;z):$$
 (6)

Because the operator G is disorder-averaged, F (z) is independent of j.

A lso, since G (z) is disorder-averaged, it can be expressed in terms of a periodic operator H $_{\rm e}~$ by the relation

$$G(z) = \frac{1}{z H_e}$$
: (7)

For the present case of \site-diagonal" disorder, H $_{\rm e}$ $\,$ can be w ritten

$$H_{e} = K_{e} + V;$$
 (8)

where K $_{\rm e}$ can be expressed as

$$K_{e} = \frac{h^{2}}{2M_{e}} X_{j} n_{j}^{2}$$
 (9)

Here M $_{\rm e}$ (z) is a complex, frequency-dependent \e ective m ass" which is, however, the same for each site j. It is convenient to express M $_{\rm e}$ in terms of two other quantities - the \virtual-crystal" m ass

$$M_{VCA} = pM_1 + (1 p)M_2;$$
 (10)

and a dimensionless, complex self-energy function (z) de ned by

$$M_{e}(z) = M_{VCA}[1(z)]:$$
 (11)

In the CPA, it is found that F (z^2) and (z) are connected by the complex scalar equation¹³

$$M_{VCA} (z) = \frac{p(1 p)(M)^2 z^2 F(z^2)}{1 + z^2 [(1 2p) M + M_{VCA} (z)] F(z^2)};$$
(12)

Here M M₁ M₂ M₂, where 1 M₁=M₂ = 1 $C_1=C_2$, and we have adopted the convention that $C_1 < C_2$.

In order to complete the approximation, we need to express F (z^2) in terms of (z). This is readily accomplished as follows. First, we consider the analogous virtual-crystal G reen's function G_{VCA} (z) 1=(z K_{VCA} V), where K_{VCA} = $_j n_j^2 = [2M_{VCA}]$. Since K_{VCA} + V is periodic, G_{VCA} (z^2) is diagonal in momentum space. In particular, the diagonal matrix element is given by

$$\ln j G_{VCA} (z^2) j q i = \frac{1}{z^2 ! q^2} G_{VCA} (q; z^2); \quad (13)$$

where $!_q$ is the frequency of a \phase phonon" of wave vector q in the vigual crystal, and jqi and jii are related by jqi = N $^{1=2}$ $_{\rm i}e^{{\rm i}q~R_{\rm i}}$ jii, R $_{\rm i}$ being the position of the ith grain and N being the number of grains in the lattice (which m ay be assumed to have periodic boundary conditions). The corresponding diagonal matrix element $F_{\rm VCA}~(z^2)$ is given by

$$F_{VCA}(z^{2}) = \frac{1}{2N M_{VCA}} \int_{q}^{X} G_{VCA}(q;z^{2}); \quad (14)$$

where the sum runs over q's in the rst Brillouin zone of the grain lattice. Next, we introduce the virtual-crystal density of states $g_{V\,C\,A}$ () by

$$g_{VCA}() = \frac{1}{2N} {X \choose q} (15)$$

in term s of which F_{VCA} (z^2) takes the form

$$F_{VCA}(z^{2}) = \frac{1}{M_{VCA}} \int_{0}^{Z_{1}} \frac{g_{VCA}(z)}{z^{2}} d : \qquad (16)$$

Finally, we can obtain F (z²) for the actual disordered crystal in terms of F_{VCA} (z²) simply by making the replacement z² ! z² [1 (z)], so that

$$F(z^{2}) = F_{VCA} \frac{z^{2} [I(z)]}{Z_{1}}$$
$$= \frac{1}{M_{VCA}} \frac{g_{VCA}(z)}{z^{2} [I(z)]} \frac{g_{VCA}(z)}{z^{2} [I(z)]} \frac{1}{z^{2}} d : (17)$$

E quations. (12) and (17) represent two coupled equations for F (z^2) and (z) which can be solved simultaneously, given a model for $g_{\rm V\,C\,A}$ ().

In the present paper, we will consider a twodimensional (2D) lattice with a simple D ebye-like density of states de ned by

$$g_{VCA}() = \frac{1}{2 v^2} (! D)$$
 (18)

 $\begin{array}{l} H \mbox{ ere } v = {\begin{array}{*{20}c} p \\ J=M_{VCA} \end{array}} \mbox{ is the speed of the \phase phonon"} \\ excitations in the virtual crystal, and (! _ D) is a unit step function. The D ebye cuto frequency \end{array}$

$$!_{\rm D} = (4 \ {\rm v}^2)^{1=2} = (4 \ {\rm J}=M_{\rm VCA})^{1=2};$$
 (19)

follows from requiring that the number of phase phonon states be normalized to one per grain. The quantity F_{VCA} (z^2) follows readily from Eq. (16):

$$F_{VCA}(z^2) = \frac{1}{M_{VCA}!_D^2} \ln \frac{z^2}{z^2 !_D^2}$$
 : (20)

E quations (12), (17), and (20) constitute a self-consistent set of equations which can now be explicitly solved to give the properties of the phase excitations in the disordered system, within the CPA.

B. Lattice properties

1. Density of states

The density of phase phonon excitations within the CPA is given by 13

$$g_{CPA}(!) = \frac{2}{!} \operatorname{Im} \int_{0}^{Z_{1}} \frac{2}{!^{2} \left[\mathbb{L} \left(! \right) \right]^{2}} d : (21)$$

U sing Eq.(18) for $g_{V\,C\,A}$ (), this expression can be further simplied to

$$g_{CPA}(!) = \frac{2}{!} \operatorname{Im} [h(x^2)];$$
 (22)

where $x^2 = (!^2=!^2_D) [1 (!)]$ and $h(x^2) = x^2 \ln x^2 = (x^2 1)$ 1. Thus, once we have obtained the self-energy from Eq. (12), we can dothe density of vibrational states, g_{CPA} (!) from Eq. (22).¹⁴

The CPA can also be used to give the component densities of states $g_{CPA}^{(\)}$ (!) (= 1,2), dened to be the average density of phase phonon density of states on grains of type . This is obtained in term softhe average diagonal matrix element G $^{(\)}$ (j; j; z²) for a grain of type . In the CPA, this matrix element takes the form $\stackrel{8}{\cdot}$

G (j; j;
$$z^2$$
) = $\frac{F(z^2)}{1 (M_{VCA} M M_{VCA}) z^2 F(z^2)};$
(23)

where $F(z^2)$ is dened in Eq. (6). The average density of states at a grain of type (norm alized so as to integrate to unity over positive frequencies) is given by

$$g_{CPA}^{()}(!) = \frac{2}{!} \operatorname{Im} \frac{h(x^{2})}{1 (M_{VCA} - M_{VCA})!^{2} F(!^{2})}; \qquad (24)$$

where x^2 and $h(x^2)$ were de ned below Eq. (22).

W ithin the CPA, the component densities of states have the pleasing property

$$pg_{CPA}^{(1)}(!) + (1 p)g_{CPA}^{(2)}(!) = g_{CPA}(!);$$
(25)

Thus, the total phase phonon density of states equals the sum of the properly weighted partial densities of states on the two species of grains. In our calculations, we have con med that this property is, indeed, satis ed for our particular choice of the D ebye m odel.

2. Spectral Function

Our self-consistent set of equations perm its calculation of another useful quantity: the spectral function, de ned by

$$\operatorname{Im} G (q;!^{2}) = \frac{!^{2} \operatorname{Im} (!^{2})}{f!^{2} (1 \operatorname{Re}[(!^{2})]) !_{q}^{2} g^{2} + f!^{2} \operatorname{Im} [(!^{2})]g^{2}};$$
(26)

The spectral function gives the frequency distribution of excitations of wave number q in the array, and, for our D ebye m odel, depends only on the m agnitude q. The full width at halfm axim um (FW HM) of the spectral function is inversely proportional to the decay time of the spin-wave-like excitations at wave vector q.

3. Mean-Square Phase Fluctuations

Finally, we can use our CPA calculations to infer the mean-square phase uctuations at the jth grain. We denote this quantity hj_j(t) \hat{j} i, where h:::i denotes a quantum -mechanical average, and _j(t) denotes the phase of the jth grain at time t. A quantum -mechanical average is appropriate at temperature T = 0. At nite temperatures, one should carry out both a quantum and a therm all average. However, such an average diverges at T \notin 0 in two dimensions (d = 2), because of contributions from the long-wavelength phase phonons. In the present discussion, therefore, we discuss only the T = 0 lim it.

We will consider the quantity hj_j(t) \hat{f} i for a lattice with Josephson coupling J and self-capacitance C_j, within the harmonic approximation. In this case, one can simply adapt the discussion of Ref. 15 for lattice vibrations in m ass-disordered system s. In fact, the present problem is slightly easier since there are no polarization degrees of freedom. To obtain this quantity, we rst use

-

a result from Ref. 15 that

$$h_{j}(t)_{k}(0)i = \frac{h}{1} \operatorname{Im}_{1}^{Z_{1}} e^{i!t}G(j;k;!^{2})d!;$$
 (27)

where, at T = 0, $G(j;k;!^2) = hjj\frac{1}{j!^2H}$ ki. The desired quantity is actually $\lim_{t!=0} h_j(t)_j(0)$ is averaged over disorder realizations, which we write

$$hj_{j}j_{dis}^{2} = -\frac{h}{m} \sum_{0}^{Z_{1}} F(!^{2})d!;$$
 (28)

where we have used the de nition of F (z^2) in Eq. (6). The operators j are computed at times t = 0 (though this average is time-independent).

We rst consider the virtual crystal lattice, in which $C_j = C_{VCA}$ for all j. In this case, hj $_j f$ is readily calculated from Eq. (28), using F_{VCA} (z) from Eq. (20), with the result

$$hj_{j} j i_{VCA} = \frac{h}{!_{D} M_{VCA}}$$
(29)

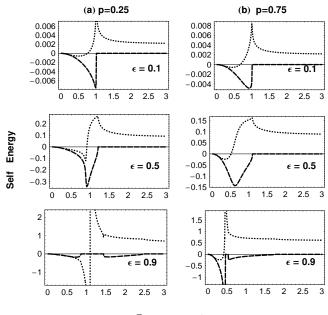

where $!_{D} = {}^{p} \frac{1}{4 \text{ J=M}_{VCA}} = {}^{q} \frac{1}{16 \text{ e}^{2} \text{J} = (\text{h}^{2} C_{VCA})}.$

For the actual disordered lattice, we can calculate within the CPA not only the full disorder average of hj $_{j}$ f i_{dis} , but also the disorder average of hj $_{j}$ f i over sites of type , which we denote hj $_{j}$ f $i^{()}$. The result is

$$hj_{j} \hat{f} i^{()} = -\frac{h}{m} \operatorname{Im}^{2} G (j; j; !^{2}) d!$$

$$Z^{0}_{j} \qquad (30)$$

$$= -\frac{h}{1} \operatorname{Im} \int_{0}^{1} \frac{F(x^{2})}{1 (M_{VCA} - M_{VCA})!^{2}F(x^{2})} d!; \qquad (31)$$

Frequency ω / ω_D

FIG.1: (a) The real (dotted line) and imaginary (dashed line) parts of the self-energy, (!), plotted as a function of the scaled frequency $!=!_D$ for three di erent cases: = 0:1;0:5; and 0:9, at a concentration p = 0.25 of light defects. Note that $!_D$ is a function of p and [cf. Eq. (19)]. (b) Same as (a) except that p = 0:75. Note the di erent vertical scales on di erent portions of the Figure.

where $x^2 = (!^2 = !_D^2) [1 (!)]$. The full hj $j \neq i_{dis}(p)$ in the CPA satis es

$$hj_{j} f_{i_{dis}}(p) = p_{j} f_{j} f_{i^{()}}; \qquad (32)$$

where the sum runs over the two species , and in our notation $p_1 = p$, and $p_2 = 1 p$.

W e can use these equations to com pute various ratios, such as hj $_{j}$ f i_{dis} (p)=hj $_{j}$ f i_{VCA} , and hence to see how the m ean-square phase uctuations increase with increasing disorder.

IV . NUMERICAL RESULTS

We have solved the model described in the preceding section to obtain the self-energy, density of states, spectral function, and mean-square phase uctuations of a two-dimensional lattice, using a Debye phase phonon spectrum. The numerical solution are obtained from straightforward iterative solution of the three selfconsistent equations (12), (17), and (20). It is important to take care that the resulting solutions are the proper physical ones, with Im (!) 0 and with both F (z^2) and (z) varying smoothly with z.

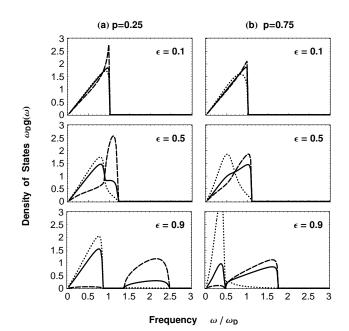

FIG. 2: (a) Normalized density of states of the phase phonon excitations, plotted as a function of the scaled frequency $!=!_{\rm D}$ calculated for a concentration p = 0.25 of low-capacitance defects and three di erent values of the disorder parameter = 1 $C_1=C_2$, as indicated in the Figure. The total density of states for phase phonon excitations, $g_{\rm CPA}(!)$, is the solid line, while the component density of states $g_{\rm CPA}^{(1)}(!)$ and $g_{\rm CPA}^{(2)}(!)$ associated with low-capacitance and high-capacitance grains are the dashed and dotted lines, respectively. The concentration of light defects (type 1) is p = 0.25. (b) same as (a) except that p = 0.75. As in Fig.1, $!_{\rm D}$ is a function of both p and Eq. (19)].

In Fig. 1 we show the real and in aginary parts of the self-energy, (!) (dotted and dashed curves respectively), plotted against the scaled frequency $!=!_{D}$, where $!_{D} = (4 \text{ J=M}_{VCA})^{1=2}$ is the virtual crystal D ebye frequency. We have carried out our calculations for two concentrations of the low-m ass defects (type 1), p = 0.25 and p = 0.75; the results are shown in Figs. 1(a) and 1(b). The three di erent panels correspond to di erent values of the ratio $1 C_1=C_2 = 0.1; 0.5;$ and 0.9. These ratios range from sm all deviations in capacitance between type 1 and type 2 (= 0.1) to large deviations (= 0.9). Note the di erences in the scales of the plots.

G iven the self-energy, several other physical quantities can be calculated, as explained in Sec. III. For example, the averaged density of states of phase-phonon excitations can be obtained within the CPA from Eq. (22), while the averaged component densities of states follow from Eq. (24). In Fig. 2 we show the average density of states g_{CPA} (!) obtained within the CPA (solid line), as wellas the component densities of states $g_{CPA}^{(1)}$ (!) (dashed

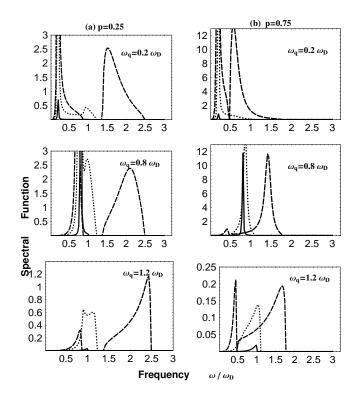

FIG.3: (a) Spectral function Im G (q;!²), plotted against the scaled frequency $!=!_{D}$ for three di erent mode frequencies $!_{q}$ as indicated in each panel. The concentration of light defects is p = 0.25. For each $!_{q}$ we have considered 1 $C_1=C_2 = 0.1$ (solid line), 0.5 (dotted line), and 0.9 (dashed line), corresponding to increasing am ounts of disorder. For $!_{q}=!_{D} < 1$, the spectral function always exhibits a single sharp peaked centered at $! = !_{q}$. (b) same as (a) except that p = 0.75.

line) and $g_{CPA}^{(2)}$ (!) (dotted line). The sum rule given in Eq. (25) is evidently satis ed by these three densities of states.

These results show characteristic features expected from CPA calculations. For the case where the capacitance of type 2 is close to that of type 1 (= 0.1), the fulland the two component densities of states are all very sim ilar, and all resemble the virtual-crystal result. As increases, there start to be more conspicuous di erences between the partial densities of states on the light-mass (type 1) and heavy-mass (type 2) grains. In particular, there is a clearly-developed band gap between the two classes of states for = 0.9. This behavior is well known as the \split-band" regime in the phonon problem. The light-mass phase phonons presumably correspond to bcalized modes, though this localization is not probed in the CPA.

In Fig. 3, we plot the spectral function de ned in Eq. (26) as a function of the scaled frequency $!=!_{D}$ for several choices of parameters. Our calculations are carried

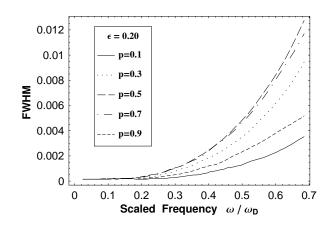

FIG. 4: The full width at half maximum (FW HM) of the spectral function, plotted versus scaled frequency $!=!_{D}$ for = 0.2, and for several concentrations p of the small-capacitance grains, as indicated in the legend.

out at three di erent mode frequencies, $!_q = !_D = 0.2$, 0.8, and 1.2, which are shown in the three di erent panels, and for two di erent defect concentrations, p = 0.25 and p = 0.75, which are shown in Figs. 3 (a) and 3 (b). In each of these cases, we have also considered three values of the mass ratio parameter: = 0.1; 0.5; and 0.9. (Note in particular the vertical scale changes in the Figures.) For $!_q = !_D < 1$, the spectral functions in all cases exhibit single sharp delta-function-like peaks centered at $! = !_q$. How ever, for $!_q = !_D > 1$, there is some spectral strength which show sup as weak peaks at higher frequencies; these are presum ably due to the localized modes in the light-m ass bands. Note also that for = 0.1 there is alm ost no spectral weight for $!_q = !_D > 1$.

In each of the cases of Fig. 3, we have also calculated the full width of the spectral function peak at halfmaximum (FW HM). This width is inversely proportional to the lifetime of the phase phonon like excitations. In Fig. 4, we plot this FW HM as a function of $!_q = !_D$ for

= 0.2, and for several concentrations of the light defects as indicated in the legend. Evidently, for a given $!_q$, the excitation lifetim es decrease, as expected, as p increases from 0 to 0.5, then increases again as p increases from 0.5 to 1. This behavior is consistent with the well-known result of second-order perturbation theory that this lifetime should vary approximately as $1=[p(1 \ p)]$ in the weak-disorder regime.⁸

Finally, we turn to the transition from phase coherence to phase incoherence in this system. If the model H am iltonian is assumed to represent an array of small Josephson junctions, this corresponds to a superconductorinsulator (S/I) transition. It is believed that superconductivity in Josephson junction arrays is destroyed when the ratio of the charging energy to the Josephson cou-

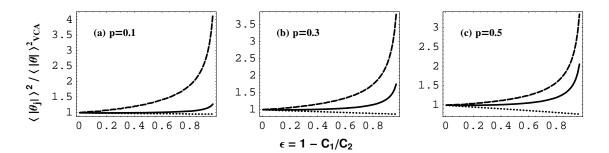

FIG.5: (a). Mean-square phase uctuation $hj_j f_{ids} = hj_j f_{iVCA}$, as evaluated in the CPA, plotted as a function of $= 1 C_1 = C_2$ for p = 0.1. The solid line shows the CPA average value, the dashed line shows the mean-square phase uctuations on a type 1 grain, and the dotted line on a type 2 grain. (b). same as (a) except that p = 0.3. (c). same as (a) except that p = 0.5.

pling energy exceeds som e characteristic limiting value.² In fact, the S/I transition is a standard example of a T = 0 quantum phase transition.¹ In two-dimensional square arrays with nearest-neighbor coupling, it has been found experimentally that the S/I transition occurs near U=J = 1:7 $(U=J)_{cr}$.²

In our discussion, we will assume a simple Lindem ann melting criterion, namely, that superconductivity is destroyed when the mean uctuations in the phase, given in Eq. (28), exceeds some lim it to be determined below. (In d = 2, such a criterion can be plausible only at T = 0, since the mean-square phase uctuation diverges at any nite T.) If all the grains have the same charging energy, then the mean-square uctuation is given by Eq. (29), which in plies a critical value of

hj j²
$$i_{cr} = (U = J)_{cr}^{1=2}$$
 1:3: (33)

Here j can be any lattice site, and we have used $(U=J)_{cr} = 1:7$.

How can this Lindem ann criterion be extended to a lattice with diagonal disorder in the charging energy? We speculate that a modi ed Lindem ann criterion may still be usable, in the following way. Let us consider the model studied in this paper, in which there are two types of grains: \light" and \heavy" (or small and large capacitance). We suggest that a possible Lindem ann criterion for destruction of superconductivity in this case is that the mean-square phase uctuations, averaged over the two types of grains, should exceed the sam e critical value as in the ordered case.

In Fig. 5 we plot the calculated ratio $hj_{i}f_{i}^{()}=hj_{i}f_{i_{VCA}}$, which gives the mean-square phase uctuations on grains of type = 1;2 with respect to those of the virtual crystal (dashed and dotted lines). We also show $hj_{i}f_{i_{dis}}=hj_{i}f_{i_{VCA}}$ which represents the average for the entire lattice (solid line). All quantities are calculated in the CPA as a function of = 1 $C_1=C_2$ for several di erent values of p, as indicated in the Figure. As expected, and as is clear

from the Figure, for all values of p, hj_i $fi^{(1)} >$ hj_i $fi^{(2)}$ because component 1 represents the light defects.

In principle, one m ight m ake an estim ate of the critical value of $(U=J)^{1=2}$ at which m elting occurs, as a function of p and , by assuming that m elting occurs when hj_ifi 1:3, as in the ordered lattice. Thus, given the properties of the lattice, one can easily extract an estimate of the melting parameters from this Figure.

V. SUMMARY

In this paper we have considered the behavior of a 2D quantum rotorm odel with diagonal disorder. In the case of Josephson junction arrays, this model corresponds to an array of sm all Josephson junctions with diagonal capacitive disorder. We have used the CPA to estimate the e ects of disorder on the phase phonon density of states, the spectral functions, and the self-energy, all within the harm onic approximation to the original Hamiltonian. Finally, we obtained a crude estimate of the parameters governing the transition from coherence to incoherence in the disordered system, using a simple Lindem ann criterion which may be applicable at T = 0.

V iew ed as a representation of a Josephson junction array (or a thin superconducting lm), our model, and our approximations used to treat it, are both very simplied representations of a real superconducting array. For example, a bim odal distribution of charging energies is oversimplied, as is our assumption of diagonal charging energies and diagonal charging disorder. In addition, we have not considered dissipation, which is known to have important e ects on S/I transitions in Josephson arrays.¹¹ N evertheless, our resultsm ay provide som e useful insights in understanding the S/I transition in such arrays, as well as the spectrum of excitations to be expected in disordered arrays.

W ould it be possible to measure experimentally the phase phonon spectrum we have calculated in this paper? It is not clear what experiment would be directly sensitive to this spectrum in a superconducting array or

In . A more promising direction might be the excitation spectrum of a Bose super uid (e.g. ${}^{4}\text{He}$) in a porous medium. Such spectra have been extensively studied experimentally, primarily using inelastic neutron scattering techniques. 4,16,17,18,19 W hile the behavior of ${}^{4}\text{He}$ in such porous media is certainly more complex than the relatively simple model discussed here, some aspects of the observed behavior (e.g., the persistence of rather sharp excitation peaks even in highly disordered system s) seem s to be mirrored in our calculated spectral functions. O bviously, a more re ned model, aim ed speci cally at the geom etries of these porous glasses, is needed before any com parison to experiment can be contemplated.

Finally, we brie y comment on the quality of the approximation itself. W hile the CPA is an excellent mean-

eld approach, it is still based on a harm onic approxim ation to the underlying H am iltonian. Ideally, it would be preferable to obtain the desired spectral functions using a m ore accurate approach, such as a quantum M onte C arlo technique (see, e.g., R ef. 20), or a version of the self-consistent phonon approximation,^{10,11} suitably generalized to treat a disordered system. We hope to return to such approaches in a future publication.
