(Dated: April 14, 2024)

M easurements are reported of the magnetic eld dependence of excitations in the quantum critical state of the spin S = 1=2 linear chain H eisenberg antiferrom agnet copper pyrazine dinitrate (CuPzN). The complete spectrum was measured at $k_B T=J = 0.025$ for H = 0 and H = 8:7 Tesla where the system is 30% magnetized. At H = 0, the results are in quantitative agreement with exact calculations of the dynamic spin correlation function for a two-spinon continuum. At high magnetic eld, there are multiple overlapping continua with incom mensurate soft modes. The boundaries of these continua con rm long-standing predictions, and the intensities are consistent with exact diagonalization and B ethe A nsatz calculations.

PACS numbers: 75.10 Jm, 75.40 Gb, 75.50 Ee

O ne of the m ost im portant ideas to emerge from studies of condensed m atter systems in recent years is the concept of quantum criticality [1]. A quantum critical point m arks a zero tem perature phase transition between di erent ground states of a m any-body system as a result of changes in parameters of the underlying H am iltonian. P recisely at the quantum critical point the system is without characteristic length scales or energy scales, with power-law spatial correlations and gapless excitations. F inite tem perature properties close to quantum criticality are anom alous and re ect universal properties of the underlying quantum eld theory.

While ne tuning of a parameter in a system 's H am iltonian is generally required to achieve quantum criticality, it is inherent to the spin S=1/2 linear chain H eisenberg antiferrom agnet (LCHAFM). The spin dynam ics of the LCHAFM have been studied in a number of materials [2, 3, 4, 5, 6], and the elementary excitations are S=1/2 spinons that form a gapless, two-particle continuum [7, 8]. In a magnetic eld, H the Ham iltonian of the LCHAFM is H = $_{i}$ [JS $_{i}$ S $_{i+1}$ g $_{B}$ H S $_{i}^{z}$]. W hile changes in H such as the introduction of dimerization or interchain coupling drive the LCHAFM away from criticality [9], the system should remain quantum critical at T = 0 in elds below the fully spin polarized state, which occurs at $H_C = 2J=g_B$ [10, 11]. Prom inent among the features predicted to exist along this quantum critical line are a set of eld-dependent twoparticle continuua [7, 12, 13, 14] with incommensurate soft modes that move across the 1D Brillouin zone with increasing eld as $q_{i;1} = 2 \text{ m}$ and $q_{i;2} =$ 2 m, where 1=2 is the reduced magnetization per spin. 0 m

Experiments on copper benzoate [15] have veried the predicted eld-dependence of the incommensurate wavevector $q_{1;2}$. How ever, due to a combination of a staggered g-tensor and D zayaloshinskii-M oria interactions,

the eld drives that system away from the critical line to a state with con ned spinons and a gap in the excitation spectrum [16]. In contrast, the nite-eld critical state of the S=1/2 LCHAFM is accessible in copper pyrazine dinitrate, Cu (C₄H₄N₂) (NO₃)₂ (CuPzN). This well characterized organo-m etallic magnet has J = 0.9m eV , and negligible interchain coupling (J $^0\!\!=\!\!J$ < 10 4) [6, 17]. The spin chains in CuPzN are uniform, with one Cu^{2+} ion per unit cell along the chain, and speci c heat m easurem ents have shown that CuPzN remains gapless forH $0:6H_{C} = 9T$ [6]. In this paper we report inelastic neutron scattering m easurem ents of the full spectrum of CuPzN, both at H = 0 and at H = 8:7 T, where m = 0.15. In zero eld, the spectrum is consistent with the exact two-spinon contribution to the spin uctuation spectrum [8]. The nite eld data show the long-sought eld-dependent continua [7], and are in detailed agreem ent with theoretical and num erical work [12, 13, 14].

The measurem ents were performed using the SPINS cold neutron triple axis spectrom eter at the N IST Center for Neutron Research. The sample studied contained 22 single crystals of deuterated C uP zN [18] with a total mass of 3.06 gram s, and a measured mosaic of two degrees. We used a dispersive analyzer con guration that detects scattered neutrons with an angular range of 10 and an energy range 2.7 m eV E_f 3.55 m eV [19]. W e used a Be lterbefore the sample for $E_i < 5:15 \text{ m eV}$, and a BeO lter after the sample. The measured full width at half maximum (FW HM) elastic energy resolution was h! = 0:14 meV, and the FW HM wave-vector resolution along the [100] chain axis was $Q_k = 0.03 \text{ A}^{-1}$ at Q = (hkl) = $(\frac{3}{2}\frac{1}{4}0)$ at h! = 0 [20]. Data were obtained along the line between $Q = (1\frac{1}{4}0)$ and $Q = (2\frac{1}{4}0)$, with H kĉ.

Figure 1 (a) shows the norm alized magnetic scattering intensity I_m (g;!) for CuPzN, measured in zero eld at

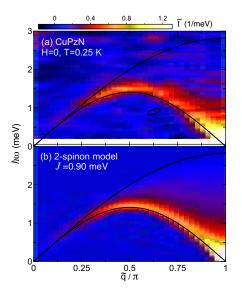

FIG.1: (a) M agnetic inelastic neutron scattering intensity I_m for CuPzN at T = 0.25 K and H = 0 versus wave-vector and energy transfer. (b) Calculated two-spinon contribution to I_m . Solid lines are the predicted lower and upper bounds of the spinon continuum . A representative FW HM resolution ellipsoid is shown in (a).

T = 0.25 K. W ave-vector transfer along the chain is represented as q = 2 (h 1), This data set was obtained by combining data taken at E $_{\rm i}$ = 3.35 m eV , 3.55 m eV , and for 3.75 meV E_i 5.75 meV with 40 V steps. After subtracting the background scattering m easured with the analyzer in a non-re ecting geom etry, the incoherent elastic scattering pro le of the sample was determined from data that were at least 0.2 meV outside of the known bounds [6] of the H = 0 spinon continuum. This pro le was scaled to to the measured elastic incoherent scattering intensity at each q, and subtracted from the raw data. The data were converted to the norm alized scattering intensity by comparison with the measured incoherent scattering intensity of a vanadium standard. The q were then averaged with that at q, binned data at 2 in bins of size h! = 25 eV by q = 0.026, and averaged over a rectangle of the same size as the FW HM energy and wave-vector resolutions to produce the color contourplot shown in Fig. 1 (a).

These data provide a complete picture of the zero-eld spinon continuum (SC) in CuPzN. The solid lines are the SC's lower and upper bounds, calculated for J = 0.9 m eV [7]. Figures 3 (a)-(c) and 2 (a)-(c) show cuts through the data, and highlight several in portant features. These include the monotonically decreasing intensity at q = [Fig. 2 (a)], the peaks near q = associated with the divergence in S (q; !) at the SC lower bound [8] Fig. 3 (a)-(c)], and the sm aller feature at low q where the SC narrows as q = 0. Figures 2 (b)-(c) show the asymmetric

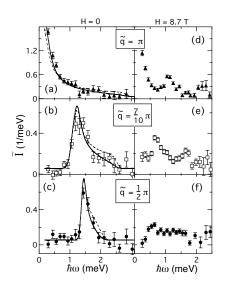

FIG.2: M agnetic scattering intensity vs h! at constant q for CuPzN at T = 0.25 K and H = 0 (a)-(c), and at H = 8.7 T (d)-(f). Each point includes scattering within a width of q = 0.05. The solid (dashed) lines in (a)-(c) are the exact (approximate) m odel for S (q; !) described in the text.

lineshapes produced by the SC for $q \in G$. Figure 3(c) also shows data taken at T = 35 K. The decrease in intensity at q = C con rms that the low-T scattering is magnetic.

Figure 1 (b) shows I_m (g; !) calculated [6] from the recently derived exact two-spinon contribution to S (g; !) [8, 21, 22] with J = 0.9 m eV, with the addition of a constant intensity xed at the average residual background measured 0.5 m eV away from the continuum. I_m (g; !) is also shown as solid lines on the cuts in Figs. 3 (a)-(c) and 2 (a)-(c). There are no adjustable parameters in the model, and the agreement with the data is excellent, although we note that there is an overall 10% uncertainty in the vanadium norm alization.

Figures 3 and 2 also show a comparison (dashed lines) to the lineshapes produced by a global t to the approxim ate form [7] for S (q; !) that has been previously used to model measurements of the H = 0 SC in CuPzN [6] and other materials [2, 3]. This approximation is now known to overestimate S (q; !) near the upper SC boundary [8, 12]. Indeed, some indications of this e ect are seen in Figs. 2 (b) and 2 (b), and although our data are not optim al for observing these di erences, the exact model does give an overall better description of the data.

The spectrum of CuPzN in a magnetic eld is considerably more complex than at zero eld, as seen in Fig.4(a), which shows I_m measured at H = 8:7 T. This data set combines data taken in the range 3.35 m eV E_i 4.75 m eV with 20 V increments, and at E_i = 5:15 m eV. An identical background subtraction, averaging, and binning procedure as used at H = 0 was applied to these data,

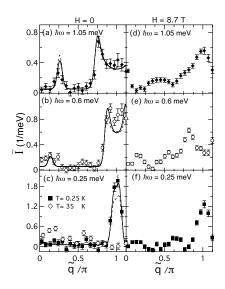

FIG.3: M agnetic scattering intensity vs q at constant h! for CuPzN at T = 0.25 K at H = 0 (a)-(c), and at H = 8.7 T (d)-(f). The data for q < have been averaged with the data at 2 q. The data displayed for q > have not been averaged in this manner. Each point includes scattering within a width of h! = 0:1 m eV. The solid (dashed) lines in (a)-(c) are the exact (approximate) m odel for S (q;!) described in the text. The scattering m easured at T = 35 K is shown as open symbols in panel (c).

using the H = 0 incoherent elastic pro le.

Several continua and prom inent features have em erged that were not present at H = 0. These are highlighted in cuts shown in Figs. 3(d)-(f) and 2(d)-(f). First, a continuum of scattering is still observed at q = -down to the low est energy probed, which demonstrates that the system indeed remains gapless and critical at H = 8:7 T. The spectrum has generally shifted to low er energy, and the strong ridge of scattering with linear dispersion near q = -has a sm aller slope than at H = 0, showing explicitly that the velocity of the elementary excitations has decreased [6].

There is a strong peak in $I_m(q; !)$ centered at q = at the eld energy $h! = g_B H$ 1:1 meV ($g_c = 2:07$ [23]). A weakerpeak at this same energy can also be seen at q = 0, which corresponds to uniform spin precession. Moving away from q =, there is another ridge of scattering intensity, which decreases in energy towards the expected eld induced incom mensurate wavevector $q_{i;2} = 0:7$. As shown in Fig. 2 (e), the incom mensurate mode is seen in increased scattering at the lowest energies probed at $q_{i;2}$ com pared to zero eld [Fig.2 (b)]. Finally, there is a mode that begins at the eld energy at q = 0, and decreases in energy with increasing q, but which loses intensity close to $q_{i;1} = 0:3$, consistent with numerical work [12].

Using the Bethe Ansatz, Muller et al. identi ed six classes of excitations out of the partially magnetized

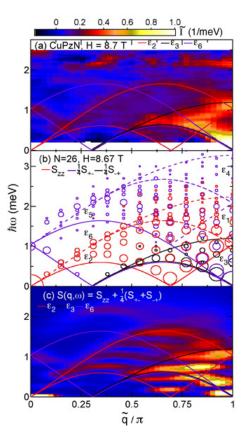

FIG.4: (a) Inelastic neutron scattering intensity I_m (g;!) for CuPzN at T = 0.25 K and H = 8:7 T. (b) Calculations of the di errent components of S (g;!) for N = 26 spins and m = 2=13 (H = 8:67 T for CuPzN). The area of each circle is proportional to S (g;!). (c) I_m (g;!) calculated for ensemble of chains with N = 24, 26, and 28. Lines show bounds of excitation continua for the nite-length S = 1=2 LCHAFM. Solid lines: continua predicted to predom inate as N ! 1.

ground state of an N -spin chain that can contribute to S (q;!) [7]. Each class produces a continuum, and M uller et al. determ ined their approxim ate boundaries. How - ever, three of these are predicted to dom inate S (q;!) as N ! 1, with (adopting the notation of Ref. [7],) class (ii) contributing to S_{zz} (q;!), class (iii) to S_{+} (q;!), and class (vi) to S_{+} (q;!). The boundaries of these three continua, E_2 , E_3 , and E_6 , are shown as solid lines in F ig.4. They closely track the principal features of the data.

W e have calculated S (eg;!) for chains of length N = 24, 26, and 28, using the Lanczos technique [12]. Figure 4 (b) depicts the results for N = 26 and m = 2=13, corresponding to H = 8:67 T for CuPzN [7]. Each eigenstate of the chain is marked by a circle with an area proportional to the corresponding contribution to S (eg;!) [12]. The circles are color-coded to indicate which component of S (eg;!) the state contributes to. Note that in our experimental geometry we measure I_m (eg;!) / $S_{zz} + \frac{1}{4}(S_+ + S_+)$. The corresponding continuum boundaries are also shown color-coded. Some spectral

weight for this nite chain is seen outside of continua (ii), (iii) and (vi), and so for reference the boundaries of the other three nite-N continua, E_1 , E_44 , and E_5 , are included as dashed lines. The nite-chain results reproduce all trends and features of the m easured intensity, and together with the continuum bounds, suggest polarization assignments.

A more direct comparison is achieved by combining the calculations in Fig.4(b) with results for N = 24, m = 1=6 and N = 28, m = 1=7, which correspond to H = 9:18 T and 8.21 T for CuPzN, respectively, and greatly increase the number of wavevectors sam pled. The results at each N were sm oothed by convolving them with the response function of a nite-size system, so that

$$S (q;h!) = \frac{X X}{N q_N} S_{N} (q_N;h!) \frac{\sin((q_1 q_N)N=2)}{\sin((q_1 q_N)=2)}^2$$
(1)

The calculated results were then converted to I_m (g;!) [6], and binned and averaged as described above. A fter multiplication by an overall scale factor, we obtain the contour plot shown in F ig. 4 (c) which represents the m easured intensity expected from an equal weighted ensemble of 24, 26, and 28 m embered spin chains. W hile the relatively short chains yield stronger discrete energy bands than in the m easurem ents, the simulation clearly captures the m ain features of the data.

Karbach and Muller have recently identied a new class of quasiparticles for the partially m agnetized S = 1/2chain. These \psinons" play a similar role in the spectrum as do the spinons at H = 0, yielding a continuum for each component of S (g;!) [13, 14], with boundaries that are consistent with the approximate analytic expressions that were used above. Karbach et al. have computed the psinon lineshapes for m = 0.25, where $q_{i:1} = q_{i:2} = = 2$. This occurs at H = 11.9 T for CuP zN, but a qualitative comparison can still be made, as the properties of the lineshapes should vary smoothly. Of particular interest is the peak at the upper boundary of the psinon continuum for S_{zz} (q;!), which is due to a singularity in the psinon density of states. This may explain the line of scattering intensity in Fig. 4 (a) that tracks the top of the E_2 continuum. This is notably di erent from the zero-eld case, where the corresponding singularity in the spinon density of states is compensated by a vanishing m atrix element, and S (q;!) vanishes at the upper boundary of the spinon continuum, as seen in Fig.1.

Finally, we note that Fig. 4(a) shows some evidence of weak scattering intensity for h! > 2 m eV. This could possibly be due to the presence of short chains resulting from in purities, or to higher-order processes not included in the spinon/psinon picture. However, we note that our error bars are much larger here than at lower energy due to shorter counting times, (see Fig. 2), and so a de nitive statement on the existence of excitations in this energy range cannot be made at this time. In sum mary, our experiments in CuPzN provide the rst experimental example of an extended critical state in a quantum magnet. This detailed mapping of the spin excitation spectrum in the spin-1/2 linear chain antiferrom agnet veri es long-standing predictions based on the Bethe Ansatz of a eld driven and critical incommensurate state. There is excellent agreement with nite chain calculations, and good qualitative agreement with the lineshapes predicted at higher elds based on novel \psinon" quasiparticles. Recent advances in Bethe Ansatz techniques show promise for full calculations of the psinons' contribution to S (q; !) [14, 24]. A direct comparison of such calculations to our data would clearly be very interesting.

This work was supported by NSF G rant No. DMR-0074571 and utilized facilities supported by NIST and the NSF under Agreem ent No. 9986442. X-ray characterization was carried out using facilities maintained by the JHU MRSEC under NSF G rant No. DMR-0080031.
