Phase diagram and critical properties are studied for three-dimensional double exchange model with and without quenched disorder. Employing the Monte Carlomethod and the systematic analysis on the nite-size elect, we estimate the Curie temperature and the critical exponent as functions of the doping concentration and the strength of the random potential. The Curie temperature well scales to the kinetic energy of electrons in the ground state as expected for this kinetics-driven ferromagnetism. The universality class of this transition is described by the short-range Heisenberg is expected for the results are compared with the experimental results in the colossal magnetoresistance manganites.

I. INTRODUCTION

Since Zener's pioneering work, the double exchange (DE) model and its extensions have been studied to understand the variety of magnetic and transport properties including the colossal magnetoresistance (CMR) in perovskite manganese oxides. 2,3,4,5 The original DE model, which contains the single-band electrons interacting with the localized spins through the Hund's-rule coupling (the Ham iltonian will be explicitly given in Sec. IIA), qualitatively explains the stability of the ferrom agnetic m etallic state and the negative magnetoresistance. There, the parallel con guration of localized spins leads to the kinetic energy gain of electrons, and vice versa. The e ective ferrom agnetic interaction between localized spins is mediated by the motion of electrons, and is called the DE interaction. Despite of the long survey for more than half century, however, the quantitative aspects of the therm odynam ics of this model have not been fully explored thus far. This is mainly because the system is in the strongly-correlated regime in the sense that the Hund's-rule coupling is much larger than the bandwidth of electrons. Both therm aland spatial uctuations are crucial in the therm odynam ics of this itinerant electron system, and they are dicult to handle in a controllable

M onte C arlo (M C) calculation is one of the power-ful tools to treat such strong correlations properly. In the present problem, since the wavefunction of itinerant electrons is extended, it is crucial to make a systematic nite-size scaling analysis for obtaining a reliable result in the thermodynamic limit. Recently, there have been some developments in the M C algorithm which enable us to handle larger size systems than ever in a reasonable computational time. 6,7,8 The importance of spatial uctuations and nite-size e ects has been ex-

am ined by comparing the MC results with the meaneld results or the dynamical meaneld approximation (DMFA) results. The reliable estimate of the Curie temperature $T_{\rm C}$ has been obtained by the systematic scaling analysis. Been obtained by the systematic scaling analysis. The critical exponents have been also estimated, and it is shown that the exponents are consistent with those of the Heisenberg spin model with short-range interactions. Phonon of the Heisenberg spin model with short-range interactions.

These previous M C calculations have been mainly perform ed at the doping concentration x = 0.5 (0.5 electrons per site on average), where the kinetic energy of electrons is maximum, namely, $T_{\mathbb{C}}$ becomes the highest. In real compounds, for instance, in La_{1 x}Sr_xM nO₃, the ferrom agnetic m etallic phase is stabilized at $0:15 \le x \le 0:6$, and T_C becomes maximum at x ' 03 and slightly reduces for x > 0.3.13 This might be due to an instability toward the A-type antiferrom agnetic state or the chargeordered state near $x = 0.5.^{14,15,16}$ These instabilities are beyond the sim ple DE m odel. The x dependence of T_{C} for 0:1 < x < 0:3 in La_{1 x}Sr_xM nO₃ has been favorably compared with the DMFA results. 17 However, the recent M C study has revealed the insu ciency of D M FA and the importance of spatial uctuations as mentioned above. One of the purposes of this work is to determ ine T_C for wide regions of x by applying the advanced M C technique and to clarify the phase diagram of the DE model. We will compare the numerical results with the experim ental results quantitatively.

A nother purpose of this work is to clarify the disorder e ect on the critical properties of the ferrom agnetic transition in the DE model. Disorder suppresses the kinetic energy of electrons and reduces $T_{\rm C}$. A lthough this reduction has been also studied by DM FA 18,19,20,21 and the MC calculation for small size clusters, 22 here we give more precise estimates employing the advanced MC method and the systematic nite-size scaling. Through

the quantitative com parison between $T_{\rm C}$ and the kinetic energy of electrons, we exam ine how the kinetics governs the DE ferrom agnetism in the disordered case. We also estim ate the critical exponent to clarify the universality class in the disordered case. These are also motivated by the experiments on the A-site substitution in AM nO $_3$ at a xed valence x which indicate the relevance of the chemical disorder of the A-site ions. 23,24,25,26 We will make a quantitative comparison between theory and experiment.

This paper is organized as follows. In Sec. II, we introduce the DE m odel including the random potential. The MC m ethod as well as the details of numerical conditions is also described here. In Sec. III, we show the numerical results. $T_{\rm C}$ and the critical exponent are estimated by the systematic nite-size scaling in both cases with and without the random potential. We discuss the numerical results in comparison with the experimental results in CMR manganites in Sec. IV. Section V is devoted to summary.

II. MODEL AND METHOD

A. M odel

The DE model considered here consists of itinerant electrons in the single band which interact with localized spins at each site through the Hund's-rule coupling. The Ham iltonian is given in the form $^{\rm 1}$

where the rst term describes the electron hopping between the nearest-neighbor sites and the second term represents the Hund's-rule coupling between the Pauli spin

of electrons and the localized spin S (the coupling is ferrom agnetic, namely, $J_{\rm H}$ is positive). Additionally, we take account of the the random on-site potential as

$$H_{"} = X_{i} c_{i}^{y} c_{i} ; \qquad (2)$$

where we consider the binary distribution, namely, "itakes the value of with equal probability random by in each site. The total Hamiltonian is given by H = $H_{DE} + H_{"}$.

In the following, for simplicity, we consider the limit of $J_H \ ! \ 1$. In this limit, the electron spin is completely parallel to the localized spin S in each site, and states with antiparallel to S are projected out. This simplies the model to the electron spin less-fermion model in the form 2

$$H = \begin{matrix} X \\ t_{ij} (e_i^y e_j + h x :) + \end{matrix} \begin{matrix} X \\ u_i e_i^y e_i; \end{matrix} (3)$$

where the transfer integral t_{ij} depends on the relative angle of localized spins at i and jth site as

$$t_{ij} = t \cos \frac{i}{2} \cos \frac{j}{2} + \sin \frac{i}{2} \sin \frac{j}{2} e^{i(i - j)}$$
: (4)

Here, the angles $_{i}$ and $_{i}$ are de ned as $S_{i}^{x} = S \sin_{i} \cos_{i}$, $S_{i}^{y} = S \sin_{i} \sin_{i}$, and $S_{i}^{z} = S \cos_{i}$, where $S = \int S_{i} j$ is the magnitude of the localized spin. Thus, the transfer integral becomes a complex variable whose amplitude is proportional to $\cos(i_{j})=2$ and phase is governed by the so-called Berry phase expf $i(i_{j})g$.

One more simplication we introduce here is to treat the localized spins in the classical limit of S! 1. Then, the present model (3) describes the strong interplay between the quantum itinerant electrons and the classical localized spins. If the configuration of the localized spins fS $_i$ g is frozen, the problem is simply the free electrons in the random magnetic eld. However, in the present problem, the localized spins are not the free external magnetic eld but internal degrees of freedom of the system. The configurations of fS $_i$ g are determined thermodynamically through the interaction with itinerant electrons. Namely, them all equilibrium is achieved to optimize fS $_i$ g which reconciles the kinetics of electrons and the entropy of the localized spins.

B. M ethod and N um erical conditions

In the following, we calculate the critical properties of the ferrom agnetic transition in model (3) dened on the three-dimensional cubic lattice. We employ the truncated polynom ial-expansion MC (TPEMC) method which is recently developed by the authors. This technique is based on the polynom ial-expansion MC method, and has advantage in the computational cost by introducing elective truncations in the polynom ialexpansion. Readers are referred to Ref. 7 for the details of the algorithm. Using this method, we calculate the physical quantities in the nite-size clusters of N = I³ from L = 6 to 16. System atic analyses on the nite-size corrections are performed for those series.

We typically perform 10000 MC samplings for measurements after 1000 steps for them alization in the absence of the disorder. The results are divided into vebins to estimate the statistical errors by the variance among the bins. In the presence of the disorder, for a given conguration of f $^{\text{H}}$ g, we typically perform 1000 MC samplings form easurements after 1000 steps for thermalization. We repeat this for typically 16 dierent congurations to estimate the errors by taking the random average among the results for each f $^{\text{H}}$ ig. We take the half bandwidth W = 6t at JH = 0 as an energy unit.

We choose twisted boundary conditions to reduce the ground state degeneracy in the <code>nite-size</code> system \hat{s}^7 by introducing the magnetic <code>ux = =4</code>, <code>=2</code>, and <code>3 =4</code> in the <code>x</code>, <code>y</code>, and <code>z</code> direction, respectively. The magnetic <code>ux is included</code> by the so-called <code>Peierls</code> factor in the phase of the transfer integrals as t_{ij} ! t_{ij} exp (i <code>=L</code>). This enables us to reach the converged results in smaller order of the polynom ial expansion. We con <code>m</code> ed that, for the range of the param eters in the present <code>w</code> ork, the

polynom ial expansion up to the 8th order is enough to obtain the exact results in the lim it of the in nite order.

In the TPEM C calculations, we take the threshold values in the truncations as 10 $\,^4$ for the m atrix product and 10 $\,^5$ for the trace operation. We cone methat the truncations with these thresholds do not change the results beyond the errors.

In the following, we calculate the magnetization at a xed doping concentration x as a function of tempera- $_{i}h_{i}^{y}e_{i}i=N$, where the bracket denotes the therm alaverage for the grand canonical ensemble.) For that purpose, we need to control the chemical potential at each tem perature because the band structure changes as magnetic correlations develop in this system .28 (The case of x = 0.5 is special because x is xed for = 0 due to the particle-hole sym metry.) Instead of this laborious procedure, we x the chemical potential so that the target value of x is realized at T T_C. This leads to T-dependence of x, however, it is small in the parameter range of interests, and does not harm the results because the magnetization is not so sensitive to the small change ofx. We con med that the magnetization does not show any x dependence beyond its errors for this small deviation of x. The values of the chem ical potential are taken as = 0.095, 0.205, and 0.310 for x = 0.4, 0.3, and 0.2, respectively. The results are shown with the errorbars of x which represent the small change of x in the corresponding tem perature range.

III. RESULTS

$\ensuremath{\mathtt{A}}$. Phase diagram in the absence of the disorder

First, we study the pure case without the random potential, namely, =0. Figure 1 shows the system-size extrapolation of the ferrom agnetic component of the spin structure factor, $S_f={}_{ij}hS_i$ $S_ji\!=\!N$, divided by the system size N. All the data well scale to $N^{2=3}$, which is consistent with the k^2 dependence of the energy cuto of magnons? From the extrapolated values, we obtain the magnetization in the thermodynamic limit as $M=\lim_{N\geq 1}\frac{1}{S_f}\!=\!\!N$.

Figure 2 sum m arizes the tem perature dependence of the m agnetization in the therm odynam ic lim it. The data for x=0.5 are taken from Ref. 10. The results are well tted by the scaling form

$$M / (T_C T);$$
 (5)

as shown by the gray curves in this gure. From these ttings, we estimate the Curie temperature $T_{\mathbb{C}}$ and the critical exponent for each value of x.

The estim ates of $T_{\rm C}$ are sum m arized in Fig. 3 (a). The results are shown also for x > 0.5 by using the particle-hole sym m etry, namely, $T_{\rm C}$ (x) = $T_{\rm C}$ (1 x). In Fig. 3 (b), the x dependence of $T_{\rm C}$ is compared with the kinetic energy in the ground state (perfectly polarized state), $E_{\rm K}$,

FIG.1: System -size extrapolation of the spin structure factor in the pure case for (a) x=0.4, (b) x=0.3, and (c) x=0.2. Sym bols at N ! 1 show the extrapolated values.

and the functional form of x (1 x) proposed in R ef. 31. The data are normalized by their value at x = 0.5 for comparison. As shown in the gure, the MC results almost scale to the kinetic energy of electrons, which comms that the DE ferromagnetism is governed by the kinetics of electrons. From this scaling, we obtain the relation $T_C = E_K = N j = 0.13$ 0.15. This enables us to estimate T_C approximately from the ground state quantity which is easily obtained in this DE system.

The estimates of by the scaling tin Fig 2 agree with the Heisenberg exponent = 0.365 (Ref. 30) within the errors for entire range of x. This is consistent with the previous MC study at x = 0.5 which has revealed that the universality class of this ferrom agnetic transition belongs to that of the short-range Heisenberg model. 9 , 10

FIG. 2: Tem perature dependence of the m agnetization in the therm odynam ic lim it. C ircles, squares, diam onds, and crosses represent the data for x=0.5;0.4;0.3, and 0.2, respectively. The data for x=0.5 are from Ref. 10. The gray curves are the scaling t by eq. (5).

FIG. 3: (a) x dependence of the Curie tem perature $T_{\rm C}$. (b) C om parison of x dependences of $T_{\rm C}$ (circles), the kinetic energy $E_{\rm K}$ (gray curve), and x (1 x) (dashed curve). All the data are normalized by their value at x = 0.5 for comparison.

B. Disorder e ect.

Next, we study the e ect of the random on-site potential at x=0.3. Figure 4 shows the system-size extrapolation of the spin structure factor by varying the strength of the random potential . Even in these disordered cases, the data well scale to N $^{2-3}$ as in the pure case in Fig. 1. This is consistent with recent studies for the spin excitation spectrum which predict the k^2 magnon excitation even in the presence of disorder. The magnetization calculated from the extrapolated values are summarized in Fig. 5. The random potential decreases the magnetization because it reduces the kinetic energy, namely, the DE ferrom agnetic interaction.

We apply the scaling of eq. (5) in this disordered case also, and obtain the estimates of $T_{\rm C}$ in Fig. 6 (a). $T_{\rm C}$ appears to scale to 2 in the weak-disorder regime. In Fig. 6 (b), we compare dependence of $T_{\rm C}$ with the kinetic energy of electrons in the ground state, and not that $T_{\rm C}$ well scales to the kinetic energy. This indicates that, also in the presence of the disorder, the DE ferromagnetism is governed by the kinetics of electrons.

From the scaling tin Fig.5, the critical exponent is also estimated. The results are shown in Fig.7. The exponent is consistent with the Heisenberg value = 0:365 (Ref. 30) even in the presence of the disorder. This indicates that the disorder is irrelevant and does not change the universality class in this transition.

IV. DISCUSSIONS

A. Comparison with La_{1 x}Sr_xM nO₃

La_{1 x}Sr_xM nO₃ near x = 0.3 has been considered to be a canonical DE system in which many aspects of the therm odynam ics are successfully explained by the DE model (1) alone. Here, we compare the estimates of $T_{\rm C}$ obtained in Sec. IIIA with the experimental values in this compound. Comparing the MC estimate $T_{\rm C}^{\rm (MC)}=0.0198W$ with the experimental value $T_{\rm C}^{\rm (exp)}=369K^{13}$ at x = 0.3, we obtain the half bandwidth as W ' 1:6eV. This value is larger than the estimates by the band calculations (W $_{\rm C}$ 1eV), $_{\rm C}^{35,36,37}$ however we note that this is the bare value in the case of $J_{\rm H}=0$ and that a large $J_{\rm H}$ generally renormalizes the bandwidth.

Figure 8 shows the comparison of x dependence of $T_{\rm C}$ between theory and experiment. We normalize $T_{\rm C}^{\rm (MC)}$ as well as the kinetic energy of electrons to agree with $T_{\rm C}^{\rm (exp)}$ at x=0.3. We note that, in the range of $0.15 \le x \le 0.3$, $T_{\rm C}^{\rm (exp)}$ well scales to the MC results and the kinetic energy. This agreement has been claimed in the DMFA results. For $x \ge 0.4$, $T_{\rm C}^{\rm (exp)}$ is suppressed and shows a deviation from this scaling. This might be due to the instability toward the A-type antiferrom agnetic state or the CE-type charge-ordered state observed near x of 5

FIG. 4: System-size extrapolation of the spin structure factor at x=0.3 for (a) = 0.05, (b) = 0.1, (c) = 0.15, and (d) = 0.2. Symbols at N ! 1 show the extrapolated values.

in m any CMR m anganites. 14,15,16 O ur data suggest that if such instabilities are absent, the C urie tem perature can become higher up to 420K.

For the critical exponents, experim ental results in this compound are still controversial. The estimates are scattered from the short-range Heisenberg ones to the meaneld ones: 0.38,39,40,41,42,43 Our results indicate that if the DE interaction plays a dominant role in the ferrom agnetic transition, the Heisenberg universality class should be observed. 9,10,11,12 Further experimental studies are de-

sired.

B. Disorder e ect in the A-site substitution

M any experiments have indicated that the disorder is important in the A-site substitution in AM nO $_3$ at a xed doping concentration^{23,24,25,26} There, the chem i-

FIG. 7: dependence of the critical exponent . The horizontal line represents the H eisenberg exponent = 0.365.

FIG. 8: Comparison between the MC results of $T_{\rm C}$ (circles) and the experimental values in La_{1 x} Sr_xM nO₃ (crosses). The kinetic energy in the ground state is also shown (gray curve). All the data are normalized to agree with each other at x = 0:3 for comparison. Triangles represent the antiferromagnetic transition temperature observed in the low x regime. Experimental data are from Ref. 13.

cal disorder from the random distribution of the A ions with di erent ionic radii is considered to disturb the electronic state in M n-O-M n network electrostatically and structurally. For instance, $T_{\rm C}$ decreases about 30% from La_{0.7}Sr_{0.3}M nO $_3$ to La_{0.7}Ca_{0.3}M nO $_3$, and this cannot be explained by the pure DE model (1) since the estinated change of the transfer integral is only about 2% 23 The MC results in Sec. IIIB shows that $T_{\rm C}$ decreases substantially by the disorder. Figure 6 (b) suggests that the 30% decrease of $T_{\rm C}$ m ight be achieved at

 $0.4\,$ 0.5. This corresponds to $0.6\,$ 0.8eV if we assum eW = 1.6eV as in Sec. IV A . The estimate of the disorder strength appears to be consistent with the potential uctuation due to the alloying e ect predicted by the band calculations. 36

The disorder e ect has been also studied in the spin excitation spectrum recently. 32,33,34 The results well explain the spectral anomalies which show up in the A-site substituted materials. 44,45,46,47 This and the above observation in the decrease of $T_{\rm C}$ consistently indicate the importance of the disorder in the A-site substitution in

CMR manganites.

In the present M C study, we consider only the diagonal disorder of the random on-site potential. In real materials, the A-site disorder may a ect the electronic state in other ways, for instance, as the o-diagonal disorder of the random transfer integrals. In the study of the spin excitation spectrum, it was shown that various types of disorder bring about the universal results in the spectrum . 32,33,34 W e speculate that this is the case also in the therm odynam ics, namely, that $T_{\rm C}$ scales to the kinetic energy and the critical exponents are for the H eisenberg universality class irrespective of the types of disorder.

For further substitution which introduces larger dierence in ionic radius, experimentally, the ferrom agnetic state is taken over by the charge-ordered state concomitant with the Jahn-Teller distortion. 14,15,16 The phase diagram shows the multicritical behavior which indicates a strong competition between dierent phases. 18,49,50 D isorder elect on the multicritical phenomena has attracted much attentions recently. 51,52,53 The emergence of the charge-ordered state suggests that, nally, another element such as the electron-phonon interaction becomes important when we approach to the multicritical point. However, we consider that, in the regime far from the multicritical point, such another element may be less important and the disorder plays a primary role.

V. SUMMARY

We have studied the phase diagram and the universality class of the ferrom agnetic transition in the threedim ensional double exchange model with and without the random potential. The truncated polynom ial-expansion Monte Carlo method has been employed to calculate large size clusters without uncontrolled or biased approximations. The Curie temperature and the critical exponent have been estimated by applying the system atic nite-size scaling analysis up to 16 site clusters. For both changes of the doping concentration and the strength of the random potential, we found that the Curie tem perature T_C well scales to the kinetic energy of electrons per site in the ground state $E_K = N$. This is a consequence of the fact that the kinetics of electrons governs the ferrom agnetism in this system. From this scaling, we have obtained the approximate relation $T_C = E_K = N j = 0.13$ 0.15, which is useful since the ground state quantity is easily calculated in the double exchange system. In both cases with and without disorder, estimates of the critical exponent are consistent with that of the Heisenberg spin model with short-range interaction. This indicates that the ferrom agnetic transition in the double exchange system s belongs to the shortrange Heisenberg universality class. We have compared the results with the experim ental results in Sr doping in La_{1 x}Sr_xM nO₃ and in the ionic radius control by the A-site substitution in AM nO 3.

A cknow ledgm ent
