(Dated: March 22, 2024)

We develop a non-perturbative numerical method to study tunneling of a single electron through an Aharonov-Bohm ring where several strongly interacting electrons are bound. Inelastic processes and spin- $\uparrow\downarrow$ scattering are taken into account. The method is applied to study microscopic mechanisms of dephasing in a non-trivial model. We show that electron-electron interactions described by the Hubbard Hamiltonian lead to strong dephasing: the transmission probability at $\mu_B = 0$ is high even at small interaction strength. In addition to inelastic scattering, we identify two energy conserving mechanisms of dephasing: symmetry-changing and spin- $\uparrow\downarrow$ scattering. The many-electron state on the ring determines which of these mechanisms will be at play: transmitted current can occur either in elastic or inelastic channels, with or without changing the spin of the scattering electron.

I. INTRODUCTION

Advances in the semiconductor technology made it possible to study quantum interference effects in mesoscopic systems where the wave nature of electrons plays an essential role. Particularly noteworthy are the studies of the Aharonov-Bohm (AB) oscillations in mesoscopic rings^{1,2,3}. The analysis of results in terms of the single-electron picture turned out to be inadequate to describe the totality of phenomena. Inelastic scattering of electrons is believed to be the predominant mechanism responsible for the loss of the phase coherence in such experiments and the suppression of the h/e oscillations. When an electron interacts with optical phonons, the dephasing only occurs through inelastic processes⁴. At low temperatures the phonon degrees of freedom freeze out, therefore other mechanisms for dephasing should be taken into account. Measurements of the dephasing time saturation at low temperatures^{5,6} show that zero-point fluctuations of the electromagnetic environment⁷ could play a role in explaining this anomalous behavior. It is nevertheless believed, that at low temperatures the electron-electron interaction is the dominant mechanism for dephasing^{8,9}. Further support for the importance of electron correlations at very low temperatures comes from recent measurements of anomalous temperature dependence of the dephasing time in mesoscopic Kondo wires¹⁰ where non-Fermi-liquid behavior has been found below the Kondo temperature.

The AB geometries have been theoretically studied using self-consistent mean-field approximations that break down for degenerate levels, which physically happens at very low temperatures^{11,12,13}. The mean-field approximation does not describe transitions in which the symmetry of the many-electron wavefunction of correlated bound electrons changes and it is thus inadequate to study dephasing. Keldysh type Green's functions and numerical renormalisation group techniques^{14,15} or equation of motion method¹⁶ have been applied to AB systems, where calculations were limited to interacting

quantum dot with two levels coupled to reservoirs. Particular attention was devoted to the appearance of the Kondo physics induced by changing the magnetic flux, however no spin- $\uparrow\downarrow$ induced dephasing has been investigated by these methods. A study of a Coulomb blockade regime was recently done by Xiong and Xiong¹⁷ with a method, similar to the one proposed in the present work. Their Hamiltonian, however, maps on a non-interacting model in the limit when the coupling to the leads is zero. Furthermore, they have only investigated spinless fermions and neglected inelastic scattering channels. Transmission of two interacting electrons was recently studied on the basis of continuous two-particle Hamiltonian where an enhancement of transmission with increasing interaction strength was found¹⁸.

To shed some new light on the problem of dephasing in electron tunneling experiments, there is obviously a demand for a capable method that would treat the problem of the scattering of an electron through a finite region where electron-electron (e-e) interactions would be exactly taken into account. Such a method should be based on the use of exact correlated many-electron wavefunctions.

In this Paper we propose a method that treats the e-e interactions by direct diagonalisation of the many-body Hamiltonian using iterative (Lanczos) technique. The method naturally takes into account spin- $\uparrow\downarrow$ processes, so it can predict the ratio of spin- $\uparrow\downarrow$ over normal scattering processes. This makes the technique interesting for calculating spin-polarized transport¹⁹ in the field of spintronics.

We apply the method to study single-electron transmission through an Aharonov-Bohm (AB) ring with e-e interactions. As it is widely known, an electron perfectly reflects from an AB ring when the flux penetrating the ring is such that the phases gained by the electron traveling through the lower or the upper arm of the AB ring cancel each other ($\Phi = \Phi_0$). Such reflection occurs for any energy of the incident electron. This remains true even when there are electrons bound on the AB ring, as long as

the system remains non-interacting. The main purpose of our investigation is in the influence of the finite Coulomb repulsion on the transmission of the electron in the case described above. We choose the Hubbard model to describe the AB ring. The Hubbard model is the simplest yet most important nontrivial prototype model for correlated electrons in the solid state. As we will show, finite Coulomb interaction in certain cases leads to finite transmission of the incident electron, despite the fact that the total wavefunction for the scattering electron and electrons bound on the AB ring preserves full quantum coherence. We will therefore refer to the processes that lead to finite transmission in the case when $\Phi = 0$ as dephasing processes since they clearly lead to diminished AB oscillations observed in experiments. We show that dephasing can occur either by a) inelastic processes where the tunneling electron excites bound electrons on the ring or by b) elastic (in regard to energy) processes, where the tunneling electron changes the symmetry or the spin of the degenerate many-electron wavefunction. No exchange of energy is required in the latter case^{19,20,21,22}: dephasing occurs because the tunneling electron leaves a trace on its "environment", which consists of bound electrons.

II. METHOD

The proposed method is based on the multichannel scattering technique that was developed for studying the tunneling of a single electron in the presence of scattering by phonons^{23,24}. Since its introduction, it has been successfully applied to a variety of problems where a single electron is coupled to phonon modes^{4,25,26,27,28,29,30,31}. It was even incorporated into Landauer theory where the influence of electron-phonon scattering on the non-equilibrium electron distribution has been investigated³². We now generalise this method to study many-electron problems.

A. Model Hamiltonian

While the method can be applied to more general situations and arbitrary geometries of the interaction region, we choose for simplicity a particular physical system which will also serve as a toy-model for the study of the e-e interaction induced dephasing. We thus consider an AB ring coupled to two ideal one-dimensional leads, see Fig. 1. The ring is described by a Hubbard-type Hamiltonian

$$H_{\text{ring}} = \sum_{j,j'} G_{jj'} c_{j,\uparrow}^\dagger c_{j',\uparrow} + \text{h.c.} + U \sum_j c_{j,\uparrow}^\dagger c_{j,\uparrow} c_{j,\downarrow}^\dagger c_{j,\downarrow} \quad (1)$$

The operator $c_{j,\uparrow}$ creates an electron with spin \uparrow at site j and we make a formal identification $c_{7,\uparrow} = c_{1,\uparrow}$.

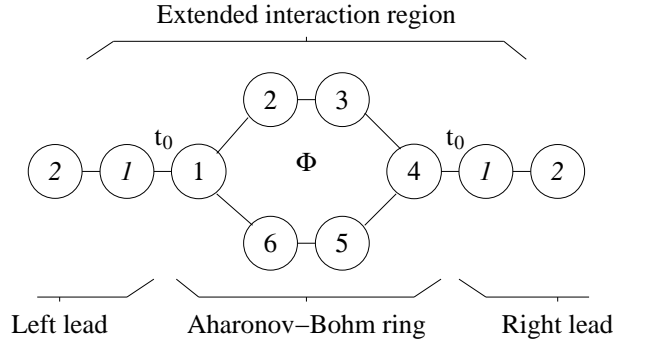

FIG. 1: Aharonov-Bohm ring. Magnetic flux penetrates the center of the ring.

The phases ϕ_j describe phase changes due to magnetic flux penetrating the ring. We chose a gauge in which we ascribe the total phase change due to magnetic field flux, $\Phi = 2\pi M/\phi_0$, (where M is the magnet field flux and $\phi_0 = h/e$ is the flux quantum) to a single element, e. g. $\phi_1 = \Phi$ and $\phi_j = 0, j \neq 1$.

The leads are described by a tight-binding Hamiltonian

$$H_{\text{lead}} = \sum_i t_{\text{lead}} a_{i+1,\uparrow}^\dagger a_{i,\uparrow} + \text{h.c.} \quad (2)$$

$$\sum_i t_{\text{lead}} b_{i+1,\uparrow}^\dagger b_{i,\uparrow} + \text{h.c.} \quad (3)$$

The operator $a_{i,\uparrow}$ creates an electron with spin \uparrow at site i on the left lead, while the operator $b_{i,\uparrow}$ does the same on the right lead. The ring is coupled to the electrodes with coupling constants t_0 :

$$H_c = \sum_i t_0 a_{i,\uparrow}^\dagger c_{1,\uparrow} + \text{h.c.} + \sum_i t_0 b_{i,\uparrow}^\dagger c_{4,\uparrow} + \text{h.c.} \quad (4)$$

The coupling constant t_0 need not be small: the method applies equally well for strong coupling between the interaction region and the leads.

B. Correlated many-electron states and exact diagonalisation

The transmittivity can be meaningfully defined in many-electron scattering problem only if one single electron leaves the scattering region. For this reason, we restrict the energy of the incoming electron to be below the ionisation threshold. Our approximation then consists of taking into account only those many-electron states in which at most one (scattering) electron is located outside the ring. Before the impact of the electron (which, for convenience, will be chosen to have spin up), there are $n = n_\uparrow + n_\downarrow$ other electrons bound on the AB ring. We truncate all many-body states, where additional electrons hop from the interacting region to the lead. When

physical parameters of the system, e.g. $(\epsilon; U)$, are chosen in such a way that these n electrons are bound in the interacting region, the approximation is equivalent to neglecting the exponentially decaying tails of the n -electron wavefunction in the leads.

Before the scattering, the bound electrons are therefore in one of the n -particle eigenstates of the Hamiltonian H_{ring} , Eq. (1). We denote these states by $|j_i\rangle$ and their energies by ϵ_i . The superscript index i denotes that the electron in the lead has spin up.

When the incoming electron enters the ring, the system is in a superposition of the $n+1$ -particle states which we denote by $|j_{i1}\rangle$. These states are not necessarily eigenstates of H_{ring} . After the scattering there is a single electron in the leads, while the ring is in a superposition of the n -particle eigenstates of H_{ring} . These states are the $|j_i\rangle$ states and (if the spin of the scattering electron can be flipped) the n -electron eigenstates with $n+1$ spin-up electrons and $n-1$ spin-down electrons. These spin-flipped states are labeled by $|j_{i\#}\rangle$ and their energies by $\epsilon_{i\#}$. Because all the possible states of the ring after scattering are orthogonal to each other, the outgoing channels are well defined and the current is conserved.

We calculate the eigenstates $|j_{i1}\rangle$ using exact diagonalisation of the Hamiltonian H_{ring} in the suitable region of the many-particle Hilbert space, taking into account that the Hubbard Hamiltonian is invariant with respect to rotations in the spin space. The diagonalisation is therefore performed in the constant $(n; S_z)$ space, where S_z is the conserved component of the total spin in the z direction. The method can be applied to Hamiltonians that don't conserve S_z at the expense of significantly more time consuming numerical calculations.

At zero temperature, the electron scatters on the ground state of the n -particle state in the ring, $|j_0\rangle$. During the scattering the electron can lose energy by exciting the bound electrons into one of the excited $|j_i\rangle$ states. The probability of such transitions is a rapidly decreasing function of the energy loss, therefore only a small number of the scattering channels (states $|j_i\rangle$) has to be considered. This observation is essential for numerical performance of the method: we can efficiently calculate the states from the bottom of the spectrum of the matrix representations of H in suitable $(n; S_z)$ subspaces using the iterative Lanczos technique. We have used the implicitly restarted Lanczos method, as implemented in ARPACK package³³. The eigenvalues and eigenvectors were computed to machine precision.

By taking into account only the allowed states, the wave-function that describes the scattering of one electron on the AB ring is given by

$$|j_i\rangle = \sum_{i=1}^X \sum_{j; } d_{i,j}^L a_i |j_{j1}\rangle + \sum_{i=1}^X \sum_{j; } d_{i,j}^R b_i |j_{j1}\rangle + \sum_j e_j |j_{j1}\rangle \quad (5)$$

where $d_{i,j}^L$, $d_{i,j}^R$ and e_k are the coefficients to be determined.

C. Reduction to a sparse system of linear equations

We consider a steady-state scattering described by the the Schrodinger equation

$$H |j_i\rangle = E |j_i\rangle \quad (6)$$

with $H = H_{\text{ring}} + H_{\text{lead}} + H_c$. Strictly speaking, this equation cannot be solved in the restricted space, spanned on the $|j_{i1}\rangle$ and $|j_i\rangle$ states, because applying the Hamiltonian to the wave-function ansatz takes us out of this space by generating terms where more than one electron can be found outside the scattering region. Omission of these terms represents the main approximation used in our method. This approximation leads to an error which is not significant for suitably chosen model parameters (see below).

Operating on the equation (6) from the left with $\langle j_{i1}|$ we obtain

$$\sum_{j; } \langle j_{i1} | b_{i,j}^L d_{i,j}^L + \sum_{j; } \langle j_{i1} | b_{i,j}^R d_{i,j}^R + \sum_k h_{i,k} e_k = E \langle j_{i1} | j_{i1} \rangle \quad (7)$$

where b 's denote scalar products

$$b_{i,j}^L = \langle j_{i1} | \mathcal{H}_{i1} | j_{j1} \rangle; \quad b_{i,j}^R = \langle j_{i1} | \mathcal{H}_{i1} | j_{j1} \rangle \quad (8)$$

while $h_{i,k} = \langle j_{i1} | \mathcal{H}_{i1} | j_{k1} \rangle$ are the matrix elements of Hamiltonian H_{ring} in the $n+1$ electron subspace.

By operating with $\langle j_{j1} |$ from the left we get

$$t_{\text{lead}} d_{2,j}^L + \sum_k \langle j_{j1} | b_{k,j}^L \rangle e_k + \sum_j d_{1,j}^L = E d_{1,j}^L : \quad (9)$$

D. Pruning the leads

In an open outgoing channel (j_{j1}) a plane wave can propagate, so that $d_{2,j}^L = \exp(ik_{j1}) d_{1,j}^L$. By energy conservation the wave number k_{j1} is obtained from

$$0 = 2t_{\text{lead}} \cos(K) = \sum_j 2t_{\text{lead}} \cos(k_{j1}) : \quad (10)$$

The energy ϵ_0 is the initial energy of the n -electron bound state on the ring, K is the wave number of the incoming electron, and ϵ_j is the final energy of the bound electrons. Equation (9) can thus be written as

$$d_{1,j}^L = \frac{\sum_k t_0 \langle j_{j1} | b_{k,j}^L \rangle e_k}{E - \epsilon_j + t_{\text{lead}} \exp(ik_{j1})} : \quad (11)$$

Similar equation can be obtained for exponentially decaying (closed) outgoing channels that we also take into

account (up to some cut-off energy, above which the inclusion of further closed channels does not change the results). These are defined through the relation $d_{2;j}^L = \exp(-i k_j) d_{1;j}^L$ and

$$0 = 2t_{\text{lead}} \cos(K) = \sum_j 2t_{\text{lead}} \cosh(k_j): \quad (12)$$

Equation (9) can in this case be written as

$$d_{1;j}^L = \frac{\sum_k t_{0-k} (d_{k;j}^L) e_k}{E - \sum_j + t_{\text{lead}} \exp(-i k_j)}: \quad (13)$$

In the incoming channel we have both the incoming and outgoing waves, $d_{m;0}^L = \exp(-i k m) + r \exp(i k m)$. We obtain $d_{2;0}^L = \exp(i k) d_{1;0}^L + \exp(-2i k) - 1$. The equation for the incoming channel thus contains an additional inhomogeneous term $\exp(-2i k) - 1$ and Equation (9) for the incoming channel is

$$d_{1;0}^L = \frac{\sum_k t_{0-k} (d_{k;0}^L) e_k - t_{\text{lead}} [\exp(-2i k) - 1]}{E - \sum_0 + t_{\text{lead}} \exp(i k)}: \quad (14)$$

Using Eqs. (11), (13), (14), and similar equations for the right lead, both leads can be removed (pruned) from the problem²⁴.

Equations (7), (11) and equivalent equations for other outgoing channels form a system of linear equations for unknowns $d_{1;j}^L$, $d_{1;j}^R$, and e_j . This sparse system is solved for different energies of the incoming electron using the SuperLU library³⁴.

The partial transmittivity through channel $(j;)$ is given by

$$T_{j;}(E) = \frac{\sin(k_j)}{\sin(K)} |d_{1;j}^R|^2: \quad (15)$$

Since the method is based on exact solution of many-electron problem, we can compute transmission at arbitrarily large values of U .

E. Extended interaction region

Results can be improved by extending the interaction region which is solved exactly by the Lanczos method by adding additional sites from the leads. This procedure takes into account the decaying tails of bound electron wavefunctions in the leads at the expense of increasing the computational Hilbert space. The error due to the omission of the terms corresponding to a second electron jumping out of the original interaction region [see discussion following Eq. (6)] is exponentially reduced with the inclusion of each additional site from the leads.

These improvements mainly lead to energy shifts of the resonance peaks while the general characteristics of the spectra remain unchanged. In principle, the region could be extended until the desired convergence is achieved. In

our calculations the interacting region consisted of the ring and one additional site from each lead, see Fig. 1. In fact, we had to take into account the site on the left electrode in order to ensure that the incident electron spreads into two partial waves that propagate through both arms of the ring. The additional site on the right electrode is required so that the partial waves can interfere, which leads to the Aharonov-Bohm effect. The inclusion of these two sites was therefore essential in our studies of the dephasing mechanism.

In cases where the ground state of the interaction region was degenerate, we averaged the transmittivity spectra over all the degenerate states. The variational space taken into account in our calculation was equivalent to a Hubbard model on 8 sites with no translational symmetry.

The largest problem that could be effectively solved has 3 bound electrons with spin up and 4 electrons with spin down. In this case there are 8000 states j_i and 5000 $j_{\downarrow i}$ states. We kept 200 lowest lying j_i states to define our scattering channels (diagonalization took 3 minutes of a modest personal computer). Solving the sparse system of complex linear equations for a range of the incoming electron energies took 200 minutes for 237 data points (or about a minute per data point on the average). This step is the most computationally demanding part of our technique. This is the main reason why we limited our calculations to 8 site models, even though the Lanczos method easily handles much larger lattices.

III. RESULTS - ONE BOUND ELECTRON

We now investigate the effect of interactions on an electron as it tunnels through the ring. The incoming electron has spin up and there is one bound electron with spin down inside the ring. The on-site energies are $\epsilon = 4.5t_{\text{lead}}$, the overlap integrals are $t = 3t_{\text{lead}}$, and we set $t_{\text{lead}} = 1$.

First we consider the non-interacting case. In the absence of the magnetic field the transmission reaches unity at the resonance, Fig. 2a. The electron is fully reflected at any incident energy when the magnetic flux is $\Phi = \Phi_0$, Fig. 2b. This is the usual Aharonov-Bohm effect.

We now turn on the interaction. At $U = 0$ we still see a unity peak at the energy of the single-electron resonance, followed by smaller satellite peaks caused by the interaction, Fig. 2c. At $U = 2$, when in the absence of U the electron is fully reflected, we obtain very high transmission probability despite relatively small $U = 0.2$, Fig. 2d. In the largest peak the transmission approaches the value $T = 1/2$. Since the incoming electron and the bound electron are not entangled, their total spin is not well defined, therefore the total wavefunction is a superposition of a singlet and a triplet state with equal amplitudes: $|j \uparrow \downarrow i = 1/\sqrt{2} (|\beta = 1; S_z = 0\rangle + |\beta = 0; S_z = 0\rangle)$. The triplet scattering has zero transmission probability at $\Phi = \Phi_0$ since in the Hubbard model only singlet elec-

FIG. 2: Transmission probability as a function of the incident electron energy for one electron with spin down bound on the ring. The incoming electron had spin up. The coupling to the lead is $t_0 = 0.4$. In all cases transmission is purely elastic.

trons interact. The singlet scattering, however, reaches the unitary limit at the main resonance peak. Averaging over both contributions, we indeed get $T = 1/2$.

The spin- $\uparrow\downarrow$ scattering part of the transmission probability is shown in the inset in Fig. 2d. The spin- $\uparrow\downarrow$ and normal scattering contribute equally to the total transmission probability. Both are purely elastic with respect to energy changes.

A. Lead decoupling at $\Phi = \pi$ and scattering mechanisms at non-zero U

To gain more insight in the mechanism of non-zero electron tunneling probability, we present a simple physical picture of electron tunneling for the case of $\Phi = \pi$. We first transform the A-B ring Hamiltonian (1) from the basis of localized states to a basis in k -space. For more generality, we can now assume that the ring consists of an arbitrary even number m of sites, which we now number from 0 to $m-1$, so that the site 0 is coupled to the left electrode, while the site $m/2$ is coupled to the right electrode.

The non-interacting part of the Hamiltonian (1) is diagonal in the plane-wave basis,

$$d_n = \frac{1}{\sqrt{m}} \sum_{j=1}^m e^{ijk_n} c_j, \quad (16)$$

with wave numbers k_n given by the periodic boundary condition $\exp(ik_n m) = 1$, or $k_n = 2\pi n/m$, where $n = 0; 1; \dots; m/2 - 1; m/2$. The corresponding eigenvalues are

$$E_n = -2t \cos(k_n - \pi/m) \quad (17)$$

When $\Phi = \pi$, all the non-interacting eigenstates are twofold degenerate since $\cos(k_n - \pi/m) = \cos(k_{1-n} - \pi/m)$. The complete orthonormal set of states is therefore composed of $m/2$ pairs of states with wave-numbers k_n and k_{1-n} for n ranging from 1 to $m/2$. For each pair we can form two linear combinations of states:

$$\begin{aligned} a_{L,n} &= \frac{1}{\sqrt{2}} (d_n + d_{1-n}) \\ &= \frac{1}{\sqrt{2m}} \sum_j e^{ik_n j} + e^{ik_{1-n} j} e^{i\frac{2\pi}{m} j} c_j; \\ a_{R,n} &= \frac{1}{\sqrt{2}} (d_n - d_{1-n}) \\ &= \frac{1}{\sqrt{2m}} \sum_j e^{ik_n j} - e^{ik_{1-n} j} e^{i\frac{2\pi}{m} j} c_j; \end{aligned} \quad (18)$$

It is easy to see that the coefficient of $c_{m/2}$ in the expression for $a_{L,n}$ is zero and likewise for the coefficient of c_0 in the expression for $a_{R,n}$. This means that the eigenstate denoted by L is coupled only to the left electrode, while eigenstate R is coupled only to the right electrode, see Fig. 3. In the non-interacting case the incoming electron can only tunnel from the left electrode to an L state. This state is decoupled from the right electrode and since there is no term in the Hamiltonian, that would allow transitions from L to R state, the electron is fully reflected.

FIG. 3: At $\Phi = \pi$, one can rotate each pair of the degenerate eigenstates in such a way that one of them couples only to the left electrode and the other to the right electrode. In absence of interactions both electrodes are effectively decoupled.

There are therefore two equivalent physical descriptions of zero transmittivity of an AB ring. One can either consider it as a destructive interference of partial electron waves that travel in the upper and lower arm of the ring, or as an effective decoupling of both electrodes due to a topological phase shift.

We will now write the interacting part of the Hamiltonian in the new basis and search for processes that are responsible for the non-zero transmission. From Eqs. (16)

and (18) we can express $c_{j;}$ as

$$c_{j;} = \frac{2e^{i(\frac{j}{m})} X^{=2}}{2m} \cos(k_n j) a_{L,jn;} + \sin(k_n j) a_{R,jn;} : \quad (19)$$

where we have introduced shifted wave numbers

$$k_n = \frac{2}{m} n - \frac{1}{2} : \quad (20)$$

The particle number operator can then be expressed as

$$\begin{aligned} c_{j;}^\dagger c_{j;} &= \frac{2}{m} \sum_{p;q} \cos(k_p j) \cos(k_q j) a_{L,jp;}^\dagger a_{L,qj;} \\ &+ \sin(k_p j) \sin(k_q j) a_{R,jp;}^\dagger a_{R,qj;} \\ &+ \cos(k_p j) \sin(k_q j) a_{L,jp;}^\dagger a_{R,qj;} \\ &+ \sin(k_p j) \cos(k_q j) a_{R,jp;}^\dagger a_{L,qj;} : \end{aligned} \quad (21)$$

We now see that the Hubbard interaction term $\sum_j c_{j;}^\dagger c_{j;}^\dagger c_{j;#} c_{j;#}$ is a sum over j of products of four trigonometric functions. Each one of these products can be written as a sum of trigonometric functions by using trigonometric reduction formulas such as, for example,

$$\begin{aligned} 8 \sin(a) \sin(b) \sin(c) \sin(d) &= \\ &\cos(a-b-c-d) + \cos(a+b-c-d) \\ &+ \cos(a-b+c-d) + \cos(a+b+c-d) \\ &+ \cos(a-b-c+d) + \cos(a+b-c+d) \\ &\cos(a-b+c+d) + \cos(a+b+c+d) : \end{aligned} \quad (22)$$

We note that reduction formulas for an even number of sine and cosine functions consist of a sum of cosine functions, while the reduction formulas for an odd number of sine and cosine functions consist of a sum of sine functions. This fact is important to understand the selection rules that lead to dephasing.

The arguments of functions on the right hand sides of the reduction formulas are sums of the form $\frac{2}{m} \sum_{j=1}^m p \frac{1}{2} - q \frac{1}{2} - r \frac{1}{2} - s \frac{1}{2}$, i.e. of form $\frac{2}{m} \sum_{j=1}^m jt$, where t is an integer. When the summation over site j is performed most of the terms will drop, since

$$\begin{aligned} \frac{1}{m} \sum_{j=1}^m \cos \left(\frac{2}{m} \sum_{j=1}^m jt \right) &= \delta_{t,0}; \\ \frac{1}{m} \sum_{j=1}^m \sin \left(\frac{2}{m} \sum_{j=1}^m jt \right) &= 0 : \end{aligned} \quad (23)$$

All interaction terms with a coefficient that after trigonometric reduction involves a sine function will therefore vanish. Such vanishing terms come from products of an odd number of trigonometric functions of each kind, therefore they are of the form such as

$$a_{R,jp;}^\dagger a_{L,qj;} a_{L,rj;}^\dagger a_{L,sj;} : \quad (24)$$

Such terms would allow (for $p = q, r = s$) transitions of the tunneling electron from state L to R without changing the bound electron state (i.e. without leaving any imprint on the environment). Such transitions would clearly be in contradiction with our understanding of the dephasing in the A-B rings.

The terms with four sine and with four cosine functions are of little importance for our purposes. They describe interlevel repulsion and interlevel transitions without changes of the L/R character of the electron states and therefore do not lead to a finite transmission. We will focus instead on terms with two sine and two cosine functions. They are of three kinds. The first one consists of terms of the form

$$a_{R,jp;}^\dagger a_{L,qj;} a_{L,rj;}^\dagger a_{R,sj;} : \quad (25)$$

These terms describe what we call symmetry-changing transitions: the tunneling electron (with spin up) in the L state jumps to a R state, while a bound electron undergoes a transition from R to L state. Such a transition can either be elastic (with respect to the energy of the tunneling electron) if $p = q, r = s$ (Fig. 4), or inelastic (Fig. 5).

FIG. 4: Transmission due to elastic symmetry-changing scattering.

FIG. 5: Transmission due to inelastic symmetry-changing scattering.

The second kind of terms is of the form

$$a_{L,jp;}^\dagger a_{L,qj;} a_{R,rj;}^\dagger a_{R,sj;} : \quad (26)$$

These terms correspond to spin-flip transitions: the tunneling electron with spin-up in the $L;q$ state makes a transition to a lower lying state $L;p$ state, while a bound electron undergoes a transition from the $R;s$ to the $R;r$ state, Fig. 6. Transition can again be either elastic (with respect to energy) for $p = q, r = s$ (Fig. 6), or inelastic (Fig. 7).

FIG. 6: Transmission due to elastic spin-↑-↓ scattering.

FIG. 7: Transmission due to inelastic spin-↑-↓ scattering.

Finally, terms of the form

$$a_{R,p;\uparrow}^\dagger a_{L,q;\uparrow} a_{R,r;\uparrow}^\dagger a_{L,s;\uparrow} \quad (27)$$

can correspond either to symmetry-changing (Fig. 8) or to spin-↑-↓ transitions (Fig. 9), depending on the $p; q; r; s$ quantum numbers.

FIG. 8: Transmission due to elastic symmetry-changing scattering (of the second kind).

B. Scattering of a wave packet

To illustrate more in detail our results presented in the previous subsection, we present here numerically exact calculation of scattering of an incoming electron (described as a wave packet with a given finite energy width) on the electron with the opposite spin, bound on the Aharonov-Bohm ring. Since we are dealing with a simple case of only two electrons, this problem can be solved numerically exactly by direct integration of the two-body Schrödinger equation $i\hbar \partial_t \psi = H \psi$. We take into consideration a sufficiently high number of chain sites, so that the positional spread of the wave packet is smaller than the length of the left and the right lead. We chose $N = 200$ sites, where the 6-site Aharonov-Bohm ring occupies positions ranging from 101 to 106.

FIG. 9: Transmission due to elastic spin-↑-↓ scattering (of the second kind).

We construct the wavefunction at the initial time as $|\psi_i\rangle = \frac{1}{\sqrt{N}} \sum_{j=1}^N \psi_{\text{packet}}(j) \psi_{\text{bound}}(j)$. The operator $\psi_{\text{bound}}^\dagger$ creates an electron with spin down in the bound eigenstate of the Aharonov-Bohm ring. We calculated this state using direct diagonalisation. The operator $\psi_{\text{packet}}^\dagger$ is

$$\psi_{\text{packet}}^\dagger = C \sum_k \exp \left(\frac{(k - k_0)^2}{2\sigma^2} \right) \exp(i k N_{\text{center}}) c_{n,k}^\dagger \quad (28)$$

where $c_{n,k}^\dagger = \frac{1}{\sqrt{N}} \sum_{j=1}^N \exp(i k j) c_{n,j}^\dagger$ and C is a normalization constant. This operator creates an electron with spin up in a wave packet centered at site N_{center} which has the average wave number k_0 and a spread of σ in the k -space. We choose $k_0 = \pi/2$ to place the wave packet in the middle of the energy band of the leads with the group velocity $v = \partial E / \partial k (k = k_0) = t = 1$. We set $\sigma = 0.13$ and $N_{\text{center}} = 50$.

The equation of motion was then integrated using Bulirsch-Stoer method, which gives highly accurate results for this type of problems. The accuracy and stability can be conveniently estimated by monitoring the deviation from the proper normalization of the wave-function. Using the Bulirsch-Stoer method the normalization differs from 1 at the eighth decimal place after the scattering.

We set the parameters to $\sigma = 3.0, t = \pi/3, t_0 = 0.6, t_{\text{lead}} = 1$. For the non-interacting system the transmittivity at $\sigma = 0$ is 0 for all electron energies, while the transmittivity of an interacting system with $U = 1$ is shown in Fig. 10. The location and the spread of the energies of the wavepacket are represented in the figure by a two-sided arrow.

The electron density before and after the scattering at $\sigma = 0$ is shown in Fig. 11 for the non-interacting case and in Fig. 12 for the interacting case³⁷. For $U = 0$, the wave-packet is perfectly reflected, as expected. For $U = 1$ the wave-packet is partially transmitted through the scattering region. In fact, the expectation value to find an electron in the second electrode, P_R , corresponds to the following average:

$$P_R = \int dk T(k) |\psi_{\text{packet}}^\dagger(k; t=0)|^2 \quad (29)$$

where the transmittivity T is calculated using the method from section II and is presented in Fig. 10. This equation

connects and thus validates the two distinct methods. It is furthermore worth stressing, that the probability of finding electrons with either orientation of spin in the second electrode is equal, see Fig. 13. This can be explained as follows: finite transmission is a direct consequence of interaction U which in the case of two electrons acts only on the singlet part of the wavefunction. The triplet part does not feel U due to the on-site nature of the interaction. Transmission therefore occurs only through the singlet channel.

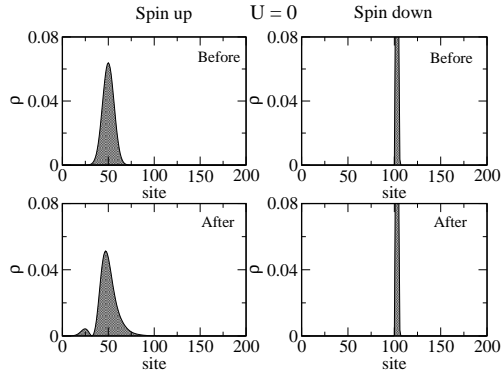

FIG. 11: Electron density before and after the scattering of the wave-packet on an Aharonov-Bohm ring at $U=0$: non-interacting case. Note that the vertical scale is the same for both spin projections: the scale was chosen so that the wave-packet is clearly visible.

C. Aharonov-Bohm oscillations

Aharonov-Bohm effect is experimentally observed as magnetic flux dependent oscillations of the electric current through a mesoscopic ring structure¹. From cal-

FIG. 12: Electron density before and after the scattering of the wave-packet on Aharonov-Bohm ring at $U=1$: interacting case.

FIG. 13: Time dependence (for interacting case) of the probability to find an electron with given spin projection either in the ring, in the left electrode or in the right electrode.

culated $T(E)$ spectra we could estimate the zero-bias conductance as $G = G_0 T(E_F)$, where $G_0 = 2e^2/h$ is the conductance quantum and E_F is the common Fermi level of both leads. In our minimal model with a discrete number of resonance states in the ring, the energy shifts of the peaks when the flux is changed (see Eq. (17)) lead to pronounced conductance variations not necessarily connected to the Aharonov-Bohm effect itself. This is a direct consequence of using a small discrete number of sites. It is therefore more revealing to observe the variations of the integral of transmittivity over the whole energy band, $\int T(E) dE$. This quantity is relatively insensitive to energy shifts of the peaks, while it should clearly show A-B oscillations which affect the height of all of the peaks.

In Fig. 14 we present this integral as a function of for a number of increasing interaction strengths $U = 0; 0.1; \dots; 1.0$. The amplitude of A-B oscillations noticeably decreases as the interaction grows stronger. Fig-

FIG. 14: The flux dependence of integrated transmission probability for different interaction strengths. The coupling to the leads is $t_0 = 0.6$, all other parameters are as before.

FIG. 15: Transmission probability as a function of the incident electron energy for n_\uparrow (n_\downarrow) electrons with spin up (down). Parameters are $\mu = 4.5$, $t = \sqrt{3}$, $U = 1.0$, $t_0 = 0.3$ and $t_{\text{lead}} = 1$.

Figure 14 also shows, that the integral transmission is essentially interaction independent around zero flux, $\Phi = 0$. A similar insensitivity of the transmission sum-rule has been discovered in the case of tunneling in the presence of electron-phonon coupling^{4,35,36}. This insensitivity breaks down at larger U .

IV. MANY BOUND ELECTRONS ON THE RING

We now consider several interacting ($U = 1$) bound electrons on the ring. All presented cases are calculated at the flux value $\Phi = 0$, unless otherwise specified. Spin of the incoming electron is up. We have limited the en-

ergy of the incident electron to a half of the bandwidth, i.e. $E = [-2; 0]$, in order to avoid ionisation. Our main goal in this section is to investigate the circumstances, under which a scattering electron obtains a finite transmission probability at $\Phi = 0$ when scattering through the AB ring in the presence of many bound electrons. We show that in most cases Coulomb interaction leads to finite transmission. In our work we refer to processes which cause finite transmission as dephasing processes. To avoid confusion we point out once more that the total wavefunction describing a many-body state of the scattering electron and bound electrons preserves its full quantum coherence throughout the calculation. Our Hamiltonian does not contain coupling to external degrees of freedom that would naturally lead to dephasing.

When the bound state on the ring consists of three electrons with spin up and one electron with spin down (Fig. 15a) no spin-flip scattering is possible because such processes turn out to be energetically impossible. The ground state is however fourfold degenerate and the tunneling electron can get through the ring at finite U by changing the symmetry of the many-electron state on the ring. Since the ground state is degenerate, this process is purely elastic.

In the case of $n_\uparrow = 0; n_\downarrow = 4$ (Fig. 15b) the ground state is non-degenerate, however the spin-flip processes are energetically allowed. We therefore obtain transmission probability only in spin-flipped channels. Since in this case the ground state is not degenerate, the transmission consists of purely inelastic processes.

In the case when the ground state is degenerate and the spin-flip processes are allowed, we expect dephasing to occur both with or without spin-flip. Such is the case of $n_\uparrow = 1; n_\downarrow = 3$, Fig. 15c. The transmission without spin-flip is purely elastic, while the spin-flip processes are predominantly elastic, with small contribution from inelastic channels.

Finally, for $n_\uparrow = 2; n_\downarrow = 2$ electrons are fully reflected from the ring since there are no allowed scattering channels in the appropriate energy interval, Fig. 15d.

We finally show the influence of large $U = 15$ on the case of $n_\uparrow = 2; n_\downarrow = 2$, where at $U = 1$ transmission remained zero in the whole interval of incoming electron energy due to widely spaced many-electron levels. At large $U = 15$ the energy difference between the non-degenerate ground state and the first excited state decreases in comparison with $U = 1$ case, as the states become compressed in the lower Hubbard band. We changed the on-site energy to $\mu = 20$ in order to keep the electrons bound on the ring. At $\Phi = 0$ there are several energies at which the electron can resonantly tunnel through the ring, Fig. 16a. At $\Phi = \pi$, the electron can only tunnel inelastically. The energy difference to the first excited state in the n electron Hubbard band is approximately 1.4. We find indeed that only the electrons that are more than 1.4 above the bottom of the energy band can tunnel, Fig. 16b. Such inelastic processes occur both without (Fig. 16c) or with spin-flip (Fig. 16d).

FIG. 16: Transmission probability as a function of incident electron energy for $n_* = 2; n_\# = 2, U = 15$ and $\alpha = 20$.

V. CONCLUSIONS

Using a simple model and a new numerical method we have investigated physics of single electron tunneling through the AB ring in the presence of correlated bound electrons. In particular we have focused on the role of electron-electron interactions on dephasing. While the proposed method clearly has some limitations (small interacting regions, inability to describe ionization processes, neglect of many-body effects in the leads), it nevertheless allows to treat the strong-interaction problem exactly and to identify the two principal microscopic mechanisms which lead to the loss of phase coherence in quantum interference experiments. We showed that a particle can tunnel through AB ring at $\alpha = \text{elastically}$ by a) changing the symmetry of the many-electron state which is possible in the case of degeneracy or b) by flipping the spin. Tunneling can also occur in the inelastic channel by exciting the many-electron state on the ring into an excited state with or without the spin-flip.

Depending on the number of bound electrons, their total spin, degeneracy of the ground state and available energy of the incoming electron, the total transmission can be composed of partial transmissions caused by either one of the listed processes.

Using the novel method we have thus unraveled microscopic mechanisms based on electron-electron interaction that in a mesoscopic system contribute to a finite transmission through the AB ring in the case of $\alpha = \text{elastically}$. However, since our method is based on small physical systems that can handle only a few lattice sites and interacting electrons we have no means at this stage to perform accurate calculation of the dephasing rate.

Even though all presented results are obtained on the basis of zero-temperature calculations, the method can be generalised to finite temperatures with some additional numerical effort. On the other hand, our results do not necessarily predict a finite dephasing rate at zero temperature. Since we treat only a single electron in the leads we are completely neglecting the effects of many-body interactions spreading from the interacting region to the electrons in the leads. This spread forms the basis for the Kondo effect. At temperatures below the Kondo temperature T_K , our approach therefore breaks down; in the Kondo regime the spins of the electrons from the interacting region couple into singlets with the electrons from the leads. This process prevents spin-flip scattering, which in our calculation represents one of the mechanisms for dephasing. Kondo coupling may also lift the degeneracy of the many-electron states in the interacting region and thus prevent transmission through the elastic channel which leads to dephasing at zero temperature according to our findings. Other mechanisms leading to dephasing in our approach might as well be modified in this low-temperature regime. We therefore conclude that despite the zero-temperature formalism used in our method, our calculations are relevant only at temperatures higher than the Kondo temperature T_K .

The method can be applied to study other many-body effects that are expected to be important in nanoscopic structures due to strong electron-electron and electron-phonon coupling. A more general implementation of the presented method is under way.
