Large di erence in the elastic properties of fcc and hcp hard-sphere crystals

Sander Pronk and Daan Frenkel FOM Institute for Atom ic and Molecular Physics Kruishan 407 1098 SJ Am sterdam, The Netherlands

We report a numerical calculation of the elastic constants of the fcc and hcp crystal phases of m onodisperse hard-sphere colloids. Supprisingly, some of these elastic constants are very di erent (up to 20%), even though the free energy, pressure and bulk compressibility of the two crystal structures are very nearly equal. As a consequence, a moderate deformation of a hard-sphere crystalm ay make the hcp phase more stable than the fcc phase. This inding has implications for the design of patterned tem plates to grow colloidal hcp crystals. We also indicate that, below close packing, there is a small, but signi cant, di erence between the distances between hexagonal layers (c=a ratios) of fcc and hcp crystals.

The simplest regular close-packed structures of hard, spherical particles are the face-centered cubic (fcc) and hexagonal close-packed (hcp) structures (see Fig. 1). C lose to melting, the Helmholtz free energies of these two crystal structures di er by less than 0.05% [1, 2, 3]. As a consequence, hard-sphere colloids (the experim ental realization of elastic hard spheres) rarely crystallize directly into the more stable fcc structure. Rather, crystallization initially results in the form ation of a random ly stacked crystal [4, 5]. The latter then slow ly transform s to the stable fcc structure [3, 6, 7, 8]. How ever, pure hcp crystals have recently been grown by colloidal epitaxy on patterned tem plates [9]. At a given density, not only the free energies, but also the pressures and com pressibilities of the fcc and hcp phases are very sim ilar. One might therefore be tempted to suppose that these two crystal phases are sim ilar in all their therm odynam ic properties. Surprisingly, this is not the case. In this Letter we present calculations of the elastic constants of fcc and hop hardsphere crystals. We show that some of these elastic constants m ay di er by as m uch as 20%. As a consequence, a moderate deform ation of the hard-sphere crystal may change the relative stability of the two crystal phases.

A hom ogeneous deform ation of a solid can be described by the transform ation m atrix $_{ij}$ that relates the cartesian coordinates x_j^0 of a point in the undeformed solid, to the coordinates x_i^0 in the deformed solid: $x_i^0 = _{ij}x_j$, where summation of repeated indices is implied. The (isothermal) elastic constants of a crystal are most easily de ned in terms of an expansion of the Helm holtz free energy F (N;V;T) in powers of the Lagrangian strains $_{ij}$ [10]:

$$F (_{ij})=V = F (0)=V + T_{ij}(0)_{ij} + \frac{1}{2}C_{ijkl ij kl} + \frac{1}{6}C_{ijklm n ij kl m n} + \dots$$
(1)

The Lagrangian strain parameters $_{ij}$ are related to the deformation matrix through $_{ij}$ $\frac{1}{2}$ ($_{ki \ kj \ ij}$). In Eq.1, the coe cients T_{ij} (0) are simply the components of the stress tensor at zero deformation, C_{ijkl} are the second-order elastic constants, $C_{ijklm \ n}$ are the third-order elastic constants, and so on. For a system under

FIG.1: Sketch of the structures of the regular close-packed fcc crystal (left) and hcp crystal (right). Inequivalent closepacked layers are labeled with the letters A,B and, in the case of fcc, C.An fcc crystal has ABCABC ::: stacking and an hcp crystal has ABABAB ::: stacking. The c=a ratio is the distance between two close-packed layers divided by the distance between neighboring particles in a close-packed layer. The gures show the de nitions of the x,y and z directions referred to in the text.

hydrostatic pressure P , the com ponents of the stress tensor are T_{ij} = $_{ij} P$.

The fcc lattice has only 3 independent elastic constants [10] (C₁₁₁₁ C₁₁, C₁₁₂₂ C₁₂ and C₂₃₂₃ C₄₄ in the coordinate fram e of the cubic unit cell). In what follows, we use this Voigt notation (C_{ij}) to denote the second-order elastic constants.

In order to compare the elastic constants of the fcc and hcp crystals, we used the coordinate system shown in Fig. 1, with the x and y directions in the hexagonal planes and the z direction perpendicular to these planes. For hcp (with hexagonal sym m etry), there are six distinct elastic constants, ve of which are independent [10]. To m ake a term -by-term comparison of the fcc and hcp elastic constant, it is convenient to ignore the full sym m etry of the fcc crystal, and only use the fact that the crystal also has a lower rhom bohedral sym m etry. If the sym m etry were really rhom bohedral, the fcc crystal would have six independent elastic constants. But, if we take the full fcc sym m etry into account, only three are linearly independent; the usual fcc elastic constants can be expressed as linear com binations of the rhom bohedral elastic constants C_{ij}^0 : $C_{11} = 4C_{11}^0$ $3C_{33}^0$, $C_{12} = C_{33}^0 + C_{12}^0$ C_{11}^0 and $C_{44} = C_{33}^0$ $\frac{1}{2} (C_{11}^0 + C_{12}^0)$.

W e computed the elastic constants by calculating the stress response to a small applied strain, using molecular dynamics simulations [11]. At zero deformation, the stress response of a system with isotropic pressure P is given by a generalization of Hooke's law:

$$\frac{\mathcal{Q} T_{ij}}{\mathcal{Q}_{kl}} = (_{ij kl} \quad _{il jk} \quad _{jl ik}) P + C_{ijkl} \qquad (2)$$

For the M D simulations, we used the event-based algorithm described by Rapaport[12]. The pressure tensor is calculated as the time average of the dyadic product of the collisional momentum exchange vector and the particle separation vector for each two-particle collision [13].

W e perform ed simulations for a range of am plitudes of each type of deform ation. The second-order elastic constants were deduced from the linear part of the stressstrain relation. In principle, all elastic constants can also be calculated in a single simulation using uctuation m ethods [14, 15, 16]. How ever, these m ethods su er from slow convergence [14]. W e found the stress-strain m ethod to be the m ost e cient.

For some deform ations, we also computed the thirdorder elastic constants from the second derivative of the stress tensor with respect to deform ation:

$$\frac{\theta^2 T_{ij}}{\theta_{rs} \theta_{tu}} = 2 t_{u rs} T_{ij} + (t_{it} t_{jr} + t_{ir} t_{jt}) T_{su}$$

$$ut (t_{ir} T_{js} + t_{jr} T_{is})$$

$$sr (t_{jt} T_{iu} + t_{it} T_{uj})$$

$$ut C_{ijrs} + t_{it} C_{ujrs} + t_{jt} C_{iurs}$$

$$sr C_{ijtu} + t_{ir} C_{sjtu} + t_{jr} C_{istu}$$

$$+ t_{rt} C_{ijsu} + C_{ijrstu}$$
(3)

T he third-order elastic constants $C_{\,\rm ijrstu}\,$ appear in the last term .

The simulations were performed on system swith 6 6 $6 = 216, 12 \ 12 \ 12 = 1728$ and $24 \ 24 \ 24 = 13824$ particles. The maximum applied deformation at lower densities was 4 10^3 ; higher densities required even smaller deformations to keep the stress response linear. The measured elastic constants between the melting point (packing fraction = 0:54329 [17]) and close packing are given in table I.

At all densities, the values of the fcc and hcp elastic constants di er signi cantly (see Fig. 2). The relative di erences between the elastic constants appear to rem ain approximately constant over the entire density range. The largest di erence between fcc and hcp (up to 20%) was found for C_{12}^0 . Yet, the compressibilities of

FIG.2: Relative di erence $j_{ab}^{0fcc} C_{ab}^{0hcp} j C_{ab}^{0fcc}$ between fcc and hcp C_{11}^{0} , C_{12}^{0} and C_{13}^{0} elastic constants as a function of packing fraction . The results shown were obtained in simulations of a system of 216 particles, with c=a = 8=3. The curves only serve as guides to the eye.

FIG. 3: Variation of the fcc and hcp free energy with deform ation (see Eq. 4). The symbols indicate the results of E instein free energy calculations (see text). The continuous curves were computed on basis of the calculated second and third order elastic constants. The error bars of the E instein free-energy calculations are about one sixth the size of the symbols. The two horizontal arrows show the predictions for f obtained by neglecting the third-order elastic constants.

the two phases are identical to within the measurement error. For instance, at melting: $K_{fcc}^{T} = 0.02422$ (5) vs. $K_{hcp}^{T} = 0.02424$ (5) (for 1728 particles). We computed these compressibilities in two ways: (a) from the appropriate linear combination of elastic constants and (b) directly from the equation of state [18]. The results are the same, to within the statistical error. At the same density, the pressures of the fcc and hcp phases are also very similar: $P_{fcc} = 11.568$ (1) and $P_{hcp} = 11.571$ (1). Finally, the free energies di er only by about 1.12 (4) 10 ${}^{3}k_{B}T$ per particle [1, 2, 3].

The di erence between the fcc and hop elastic constants is surprising because, already in 1967, Stillinger

TABLE I: Second-order elastic constants of fcc and hop hard-sphere crystals at densities between the melting point and close packing. The values for the hop structure with $c=a = \frac{1}{8=3}$ are shown in upright font. The (almost identical) results for a fully relaxed c=a ratio: $c=a = \frac{1}{8=3}(1 \ 7.5 \ 10^4)$ at = 0.543, are shown in italics. The simulation equilibration time was 1 10 collisions per particle. D ata were collected during typically 2 10 collisions per particle for the 216 particle system , and 6 10 collisions per particle for the 13292 particle system. For each deform ation, 8 simulations were done at di erent strain amplitudes to check linearity of the stress response. The calculations of the stress-strain curve for each type of deform ation involved simulations totaling several billion collisions 6:4 10 collisions (one week on an Athlon 1600+ CPU).

and Salsburg [19] had pointed out that a simple freevolum e m odel predicts that the fcc and hcp elastic constants should be equal. However, they also showed that pair and triplet correlation e ects can lead to di erences. Still, we were surprised by the magnitude of the com puted di erences, in particular for C_{12}^0 . To double-check our calculations of the elastic constants, we perform ed a second, fully independent calculation where we directly com puted the free energy of the crystals in various states of deform ation. The free energy of the (deform ed and undeform ed) crystals was calculated using a 20-point E instein integration [17]. W e found that the results obtained by the two methods were completely consistent. For example, in Fig. 3, we show the results of the two calculations for free energy change due to a deform ation of the form

To lowest order in , $F = V = (2T_{xx} + C_{11} - C_{12})^2$, for

FIG.4: Equilibrium anisotropy $(1 \frac{c}{a} = \frac{p}{\frac{b}{3}})$ for the hcp hard sphere crystal as a function of packing fraction.

this deform ation. As the gure shows, the di erences in elastic constants C_{11}^0 and C_{12}^0 , for fcc and hcp, are so large that a deform ation of 12% is enough to make hcp more stable than fcc. The free energy increase of the fcc phase due to a deform ation of 2% is $f_{fcc} = 1.93(1) \ 10^2$, while for hcp it is only $f_{hcp} = 1.66(1) \ 10^2$. Fig. 3 also shows the e ect of the third-order elastic constants. To within the statistical accuracy of our simulations, the relevant third-order elastic constants (see table II), were found to be the same for fcc and hcp. Hence, they do not a ect the free energy di erence between the two lattices.

For the undeform ed fcc system , all three diagonal com – ponents of the pressure tensor are equal. However, this does not hold for a hop system at the same c=a-ratio

(i.e. for the sam e spacing between the close packed [111]planes). If we x the c=a ratio at the fcc value (8=3), the stresses exhibit a slight anisotropy. For the 13292 particle system T_{xx} and T_{yy} are equal (as they should): $T_{xx} = 11:587(1), T_{yy} = 11:588(1).$ However, T_{zz} is signi cantly di erent: $T_z = 11:537(1)$. From Eq.1, we can derive what change in the c=a ratio is needed to m ake the pressure isotropic. We pd that, at melting, isotropy is restored for a c=a ratio of $\frac{1}{8=3}$ (1 7.5(2) 10⁴). At higher densities, this value approaches the close packing 8=3, as can be seen in Fig. 4. Stillinger and value c=a = Salsburg [19] used the cell-clusterm ethod to estim ate the di erence of the fcc and hcp c=a ratios. Our simulations show that, close to melting, the e ect is one order of m agnitude larger than predicted. The free energy di erence between the equilibrium hop and fcc crystals is only slightly changed by this relaxation of the hop c=a ratio: it becom es 1:050(5) $10^{3}k_{B}$ T perparticle for N = 13292 at melting.

As can be seen from the results in table I for = 0:543 | where the c=a ratio di ers most from fcc | the e ect of relaxing c=a to its equilibrium value, is barely signi cant. For this reason, most hop elastic constants in table I were computed for c=a = $\frac{1}{8=3}$. The table

also shows that the elastic constants depend som ew hat on system size, but the e ect is too sm all to change the qualitative picture.

In colloidal-epitaxy experiments [9], the best hcp crystals were obtained when the patterned template was stretched by 2:6% with respect to the expected lattice spacing at the experimental packing fraction (= 0:68). The templates used matched a diagonal cut through the xy plane of F ig. 1. Together with the stress produced by gravity (resulting in a strain perpendicular to the tem – plate plane of 2:8%), this strain is comparable to the strain of Eq.4 and would result in a free energy di erence of about 3 $10^2 \rm k_B$ T per particle in favor of hcp. The present simulation results may help experimentalists in designing optim al templates to grow selectively colloidal hcp or fcc crystals.

We thank Jacob Hoogenboom (Universiteit Twente) for inspiring discussions about his experimental work. The work of the FOM institute is part of the research program of the Foundation for Fundam ental Research on M atter (FOM) and was made possible through nancial support by the D utch Foundation for Scienti c Research (NWO).
