(Dated: April 14, 2024)

The e ect of a periodic pinning array on the vortex state in a 2D superconductor at low tem peratures is studied within the fram ework of the G inzburg-Landau approach. It is shown that attractive interaction of vortex cores to a commensurate pin lattice stabilizes vortex solid phases with long range positional order against violent shear uctuations. Exploiting a simple analytical method, based on the Landau orbitals description, we derive a rather detailed picture of the low tem peratures vortex state phase diagram. It is predicted that for su ciently clean samples application of an articial periodic pinning array would enable one to directly detect the intrinsic shear stiness anisotropy characterizing the ideal vortex lattice.

I. IN TRODUCTION

The nature of the vortex lattice melting transition in 2D superconductors has been debated in the literature for many years<sup>1</sup>. Early proposals<sup>2;3</sup>, based on the sim ilarity to the K osterlitz-T houless H alperin-N elson-Y oung theory of melting in 2D solids<sup>4</sup>, have led to the conclusion that the melting transition is continuous. A weak

rst orderm elting transition was predicted m ore recently, how ever, by several M onte C arlo sim ulations<sup>5;6</sup> using the G inzburg-Landau (G L) theory. It has been shown recently<sup>1;7;8</sup> that shear m otions of B ragg chains along the principal crystallographic axis of the vortex lattice cost a very sm all fraction of the SC condensation energy and are responsible for the low tem perature vortex lattice m elting.

This intrinsic anisotropy of the vortex lattice with respect to shear stress can not be easily detected experim entally since the orientation of the principal axis with respect to the laboratory fram e depends on the local pinning potential, which in real superconductors is usually produced by random distribution of pinning centers. Indirect experim ental detection of this hidden an isotropy may be achieved by means of the small angle neutron scattering (SANS) technique, due to the 1D nature of the e ective thermal uctuations in the vortex liquid state just above the melting point (see Ref.<sup>8</sup>). A direct detection of this anisotropy (e.g. by means of SANS) could be possible if vortex solid phases with long range positional order were stabilized against the random in uence of pinning impurities. This can be achieved by exposing the SC sample to an articial periodic pinning array and tuning the magnetic ux density to an integer multiple of the pinning centers density. As will be shown in this paper, under certain conditions the arti cial periodic pinning potential can stabilize weakly pinned vortex solid phases with long range positional order, which may exhibit the shear sti ness an isotropy characterizing the

ideal vortex lattice.

Vortex m atter interacting with periodic pinning arrays is currently a subject of intense experim ental<sup>9</sup> <sup>16</sup> and theoretical<sup>17</sup> <sup>23</sup> investigations. Developments of nano-engineering techniques, such as e-beam lithography, m ake it possible to fabricate wellde ned periodic arrays of submicron antidotes, or m agnetic dots, in SC Im s with low intrinsic pinning, enabling to study the elect of well controlled articial pinning centers. These experiments have show n that under certain conditions the underlying arti-

cial pinning centers can attract vortices very strongly, thus stabilizing vortex patterns with global translational sym m etry against the random ize in uence of the natural pinning centers.

From theoretical point of view the utilization of an external periodic pinning potential provides a convenient tool for testing di erent models of the vortex state by simplifying considerably the model calculations. At the same time, however, the interplay between the vortexvortex interactions, which favor hexagonal vortex lattice symmetry, and the underlying periodic potential can lead to a variety of vortex con gurations, depending on the pinning strength, in which vortices detach from pinning centers to form more closely packed vortex patterns.

As the interaction with a periodic substrate stabilizes the vortex system versus therm al uctuations, it generally increases the melting temperature. However, as we shall see in this paper, deviation from the ideal hexagonal symmetry due to pinning reduces the phase dependent interaction between vortex chains<sup>8</sup>, making them less enduring under therm al uctuations. In the weak pinning limit, where depinned oating state can occur, the corresponding phase diagram becomes rather com plicated, due to the possibility of transitions between oating solid and pin solid phases<sup>22</sup>.

In the present paper we study the in uence of a periodic pinning substrate on the vortex state in 2D, extrem e type II superconductors, at perpendicular high m agnetic elds. Our approach is based on the previously developed theory of vortex lattice melting in pure superconductors  $(^{1;7;8})$ , carried out within the fram ework of the G L theory in the lowest Landau level (LLL) approximation. Specializing the calculation for a vortex system interacting with a square pinning array under the st matching magnetic eld, we study in detailsom e key limiting regions of the vortex phase diagram, which enables us to determ ine its main qualitative features.

#### II. THE MODEL

We consider a 2D superconductor at high perpendicular magnetic eld, interacting with a periodic substrate of pinning centers, located at  $(x_i; y_j)$ . A phenom enological G inzburg-Landau functional, with an order param eter (x; y), is used to describe the superconducting (SC) part of the free energy, and a local periodic pinning potential<sup>24</sup>:

$$V_{\text{pin}} = v_0 \qquad j \quad (x_i; y_j) \qquad j \qquad (1)$$

determ ines the interaction of the vortex state with pinning centers. We assume  $v_0 > 0$ , so that the pinning energy is minimal if the vortex core positions, determ ined by  $(x_i;y_i) = 0$ , coincide with pinning centers.

O urm ain interest here is in the in uence of the pinning potential on the vortex lattice melting process, so that the pinning energy  $V_{pin}$  is restricted to the range of the vortex lattice melting energy, which is much smaller than the SC condensation energy. Since the latter is of the same magnitude as the cyclotron energy, it is justiled to restrict the analysis to the LLL of the corresponding SC order parameter, which can be therefore written as a linear combination of ground Landau orbitals:

$$\begin{array}{rcl} x & & & \\ (x;y) & = & & \\ c_{n} & q_{n} & (x;y) & \\ & & \\ c_{n} & = & j_{n} \\ \dot{g} e^{i' n}; & & \\ q & (x;y) & = & e^{2iqx (y+q)^{2}} \end{array}$$
 (2)

where  $q_n = qn$ ,  $q = =a_x$ , and the amplitudes  $c_n$  in the mean eld approximation are related to the (spatial) mean square SC order parameter,  ${}^2_0$ , through:  $\dot{p}_n \dot{f} = c_0^2 = \frac{2q^2}{2} {}^2_0$ . In our notations all space variables are measured in units of magnetic length.

In this model, due to the G aussian attenuation along the y-axis over a characteristic distance of the order of the magnetic length, the vortex cores (located at the zeros of (x;y)) form a network of linear chains along the x-axis, each of which is determ ined mainly by a superposition of two neighboring Landau orbitals<sup>8</sup>. The parameter  $a_x$  is therefore equal to the inter-vortex distance within a chain, while  $=a_x$  is the inter-chain spacing in the y-direction (see Fig. 1). It should be noted that deviations of Landau orbital (LO) amplitudes from

FIG.1: Schem atic arrangem ent of a vortex lattice relative to the pin lattice.

their mean eld value, q, resulting in strong local distortions of the super uid density and large increase of the corresponding free energy density, are neglected in comparison with variations of the phase variables,  $\prime_n$ , provided the orbital direction is selected to be along the principal crystallographic axis<sup>7;8</sup>.

 ${\tt W}$  e select the pinning centers to form a rectangular lattice

$$(x_i; y_j) = (l_x i + x_0; l_y j + y_0)$$
 (3)

where i; j = 0; 1; ..... The parameters  $x_0$  and  $y_0$  determine the relative position of the pin and vortex lattices. The nature of the vortex state in the presence of the pinning potential depends crucially on the ratio of the number of vortices, N = N N, to the number of pinning centers, N<sub>p</sub> = N<sub>pix</sub> N<sub>piy</sub>. Since the density of vortices depends on the external magnetic eld strength H, one can tune this ratio by varying H. Of special interest are the matching elds H = H , = 1;2; ..., when the ratio n N = N<sub>p</sub> = is an integer.

In matching elds one may distinguish between two di erent situations, when vortices are bound or unbound to pinning centers. If the pin lattice and the vortex lattice unit cells are commensurate along both x and y directions, i.e.  $l_x = c_x a_x$ ,  $l_y = c_y = a_x$ , with  $c_x$  and  $c_y$  being integers, the pinning energy is equal to zero, since all the vortices coincide with pinning centers. In all other cases of matching elds,  $gc_y =$  integer, non of the numbers  $c_x$  1 and  $c_y$  1 can be integer, and the lattice constants are incommensurate in both directions. It will be shown below that such a vortex con guration is in a oating state with respect to the pin lattice, sim ilar to vortex states in m ismatching magnetic elds.

U sing the LO representation, Eq.(2), of the SC order parameter in Eq.(1) for the pinning energy, one may take advantage of the localized nature of the LO s and expand  $V_{pin}$  in the small parameter =  $e^{q^2}$ , which recets the small overlap integral between adjacent orbitals contributing to the local super uid density at the pinning centers. Retaining only dominant terms in Eq. (1) is reduced to the form :

$$V_{pin} = V_{0}^{r} \frac{2q^{2}}{2q^{2}} X \qquad u_{k} + 2 \qquad e^{q^{2}m^{2}=2} u_{k+m=2-k,m}$$

$$r \frac{r}{2q^{2}} X \qquad h \qquad i$$

$$v_{0} \frac{2q^{2}}{2q^{2}} X \qquad h \qquad i$$

$$u_{k+m=2} = \frac{1}{N_{p/Y}} X \qquad e^{2(y_{j}+q(k+m=2))^{2}}$$

$$k_{m} = \frac{1}{N_{p/X}} X \qquad \cos(t_{k+m} \qquad t_{k} + 2m qx_{i})$$

where  $V_0 = v_0 {}^2_0 N_{p,x} N_{p,y}$ . It should be stressed that this approximation is valid only for LOs along the principal axes since them inimal distance between them,  $q = = a_x$ , is su ciently large to ensure small and rapidly decreasing value of the overlap integrals between more distant orbitals.

If  $c_x$  is not an integer, namely the rectangular pin lattice and vortex lattice are incom mensurate in x-direction, then Eq.(4) shows that  $k_{m} = 0$ . In this case the pinning energy does not depend on the phases (i.e. the relative horizontal positions) of the Landau orbitals.

Expressing the functions  $u_k$  and  $u_{k+\;l=2}$  with the help of Poisson sum mation form  $u\,la$  as

$$u_{k+m=2} = \frac{1}{N_{p;y}} X_{j} e^{2(l_{y}j+y_{0}+q(k+:5))^{2}} \frac{1}{N_{p;y}} \frac{1}{2l_{y}^{2}}$$

$$\frac{1}{2} Y_{j} = \frac{2}{2l_{y}^{2}} x_{j} e^{\frac{2}{2}l_{y}^{2}} e^{\frac{2}{2}l_{y}^{2}} x_{j} e^{\frac{2}{2}l_{y}^{2}} e^{\frac{2}{2}} e^{\frac{2}{2}l_{y}^{2}} e^{\frac{2}{2}} e^{\frac{2$$

we note that when the lattices are incom m ensurate also along the y axis (i.e. when both  $c_x$  and  $c_y$  are not integer) the oscillating terms in  $u_k$  are averaged to zero after sum m ation over k. Thus, the pinning energy for incom m ensurate lattices is a constant

$$V_{pin} = V_0 \frac{q N}{l_y N_{pyy}} = V_0$$
(6)

which does not depend on the mutual orientation of the vortex and the pin lattices. Note that the system size in y direction is  $L_y = q N = l_y N_{py}$ , a relation connecting  $\frac{1}{N}$  to  $N_{py}$ . Obtained result is valid only for large system, N = 1, where the boundary elect can be neglected.

For the sake of simplicity, we will consider in what follows a square pin lattice with n = 1. In the commensurate situation the pinning energy ism inim al (i.e. equal to zero) when all vortices coincide with pinning centers. D eviations of vortices from this con guration in the form of shear distortions along the principal crystallographic axes are of special interest due to the relatively low SC energy involved. For the principal axis parallel to a side of the square unit cell,  $c_x = c_y = 1$  and  $q^2 =$ , and so, according to Eq. (4), the pinning energy per single

vortex is, up to small terms of the order  $e^2$  , given # by:

$$\frac{V_{pin}}{N} = v \frac{1}{N} X_{k} [a_{1} a_{2} \cos('_{k} '_{k 1})] ' v \frac{1}{N} X_{k} [1 \cos(k)]$$
(7)

where v = V<sub>0</sub>=N ,  $a_1 = 1$  2e <sup>=2</sup> ' :584 and  $a_2 = 2e^{-2}$  1 + 2e <sup>=2</sup> ' :589 . Note that in the above (4) expressions we set  $x_0 = y_0 = q=2$  so that the minimal pinning energy is obtained for k = 0. Note also that for the undistorted square lattice in which  $'_{k} = '_{k,1}$ , the expression in the st line of Eq. (7) is not strictly zero since  $a_1 \in a_2$ . The error, which is of order higher than the second in e , can be neglected in the approxim ation leading to Eq. (7). The numbers  $a_1; a_2$  can be thus considered equal within this approximation, allowing us to introduce a single coe cient  $x = a_1 ' a_2 ' :59$ . The expression in the second line of Eq. (7) yields the correct (i.e. zero) value for the undistorted lattice. It is written in terms of the variables,  $_{k}$   $'_{k}$   $'_{k-1}$ , describing the lateral positions of the vortex chains, which are generated mainly by interference between two neighboring LOs. This is consistent with the well known de nition  $u_x = 0' = 0$  of vortex displacement along the x axis in the long wavelength  $\lim it^{25}$ .

To evaluate the excess pinning energy associated with shear distortion along the diagonal of the square unit cell the pin lattice may be conveniently described by two interpenetrating simple square sub-lattices with  $c_x = 1$ ;  $c_y = 2$  and  $q^2 = 2$  (see Fig.2). The corresponding interchain pinning energy for each of the sublattices can again be obtained from Eq. (7), with  $x^0$ ' \$4 and a phase shift of =2, which arises due to di erent shape of the unit cell.

The SC part of the free energy functional for the com – mensurate lattices described above ( $a_x = \frac{P}{}$ ) is given by the following ( $_k$ -dependent) expression<sup>7</sup>:

$$\frac{H_{sc}}{N} = h_2 \quad T_2 \frac{1}{p} \frac{1}{N} \begin{bmatrix} I & \cos(k+1) & k \end{bmatrix}$$
(8)

where  $h_2$  is the SC condensation energy (per unit  $\,$  ux) of the square vortex lattice, and  $T_2 = \frac{4}{1+4} \frac{2}{sq} h_2$  is the shear distortion energy parameter, expressed through the dimensionless interchain coupling constant,  $_{sq} = \exp($ ). Here  $h_2 = "_0 \frac{\Lambda}{sq}$ , where  $_A$  ' 1:159 and  $_{sq}$ ' 1:18, are the values of the Abrikosov structure parameter for regular hexagonal and square lattices respectively, and "\_0 is the SC condensation energy of the form er.

For the speci c choice  $_{k} = k$ , where is a constant, the Bragg family of vortex chains along the principal axis, denoted x, is characterized by a lateral displacement,  $_{k+1} = k =$ , between neighboring chains. Evidently, the SC energy, H  $_{sc}$ , for the undistorted square vortex

FIG.2: Primitive and none-primitive unit cell representations (solid and dotted lines respectively) of the square pin lattice used for description of shear distortion along the principal axes of the vortex lattice.

lattice  $_{k} = 0$  ( = 0) (see Eq. (8)), is equal to N h<sub>2</sub>. However, the minimum of the SC energy with respect to the collective tilt angle parameter is reached for a triangular vortex lattice, determined by  $_{k} = k$  ( = ), whose unit cell is an isosceles triangle with a base (along x-axis) and a height equal to  $^{P}$  (see Fig. 3). The corresponding SC energy is equal to H  $_{sc}$ =N = h<sub>2</sub> 2T<sub>2</sub>. This value is lower than the SC energy of the square vortex lattice, and only slightly higher (i.e. by .45%) than the SC energy of the equilateral triangular (A brikosov) lattice, H  $_{4}$ =N =  $"_{0}$ .

### III. VORTEX STATES FOR THE LOW EST M ATCH ING FIELD

## A. Commensurate and incommensurate G round states

The competition between the pinning energy, Eq. (7), which favors vortices approaching the pinning points on a square lattice, and the SC energy, Eq. (8), preferring triangular lattice con guration, leads to 'fustrated' vortex structures, which depend on the relative pinning strength.

At zero temperature they can be obtained by minimizing the total energy, consisting of the SC and pinning parts. Since in the LO representation each orbital is  $\overline{N}$  - fold degenerate, the e ective H amiltonian is written as:

$$f_{2} = \frac{H_{sc} + V_{pin}}{N} = \frac{T_{2}}{P \frac{1}{N}} \begin{pmatrix} X & n \\ h_{2} = T_{2} \end{pmatrix} \\ + 4p [L \cos(k)] [L \cos(k+1 - k)] \quad (9)$$

where the parameter p  $_xv_2=4T_2$  determines the strength of the pinning potential relative to the intervor-

FIG.3: (a) The vortex lattice state with the lowest energy, which is commensurate with a square pinning lattice in the limit of zero pinning strength. (b) An alternative vortex lattice state, which may be favorable under square framework boundary conditions (see text).

tex chain coupling. Under the constraints in posed by the requirem ent of commensurability between the vortex conguration and the pin lattice, the vortex chains are restricted to move laterally along the common x-axis of the underlying lattices (see Fig. 1). The corresponding displacements,  $_k$ , may be separated into two groups, corresponding to even and odd vortex chains, as follows:

$$_{k} = \begin{array}{c} 1 & \text{for } k = 21 \\ 1 & \text{for } k = 21 & 1 \end{array}$$
(10)

so that

$$f_{2} = \frac{T_{2}}{N} \frac{X ^{n}}{1} 2h_{2} = T_{2} + 4p [2 \cos(1) \cos(1)]$$

$$[2 \cos(1 + 1) \cos(1 + 1)]$$
(11)

The calculation m ay be greatly simpli ed if we assume that the stationary point values within each group are all equal, that is:  $_1 = _c$  and  $_1 = _c$ . This restriction may be justilled in the weak pinning regime 0 , wherethe dom inant SC energy part favors periodic triangularvortex structures, as shown in Fig. 3a.

Substituting these values to Eq. (11) and m inim izing the resulting functional one nds that the total energy has a m inim um :

m in (f<sub>2</sub>) = 
$$\frac{1}{p_{m_k}}^X 2T_2 (1 p)^2 + h_2$$
 (12)

at  $_{c} = _{c} = _{0}$  where

$$\cos(_{0}) = p:$$
 (13)

Thus, at zero pinning strength, p = 0, the ground state energy per unit ux,  $f_2 = 2T_2$  h<sub>2</sub>, corresponds to a triangular vortex lattice con guration,  $_c = _c = =2$ , whereas in the opposite extreme, when p = 1, the ground state energy,  $f_2 = h_2$ , corresponds to a square vortex lattice,  $_c = _c = 0$ , which coincides with the underlying pin lattice. It should be stressed, how ever, that due to the constraints in posed by the requirem ent of com m ensurability with the pin square lattice, the triangular vortex structure obtained in the zero pinning strength limit, is not the equilateral (A brikosov) lattice (see Fig.3a). This discontinuity indicates that the transition to the depinned ( oating) vortex lattice should be of the rst order (see below).

An illustration of the weak pinning ground state conquration is shown in Fig. 3a. It is seen that odd and even vortex chains are shifted in opposite directions sym m etrically with respect to the underlying substrate. The relative positions of the two lattices are determ ined by the strength of the pinning potential,  $V_0$ . In the zero pinning lim it,  $V_0$  ! 0, the vortices in odd (even) chains approach lattice points which are shifted laterally by a quarter of a lattice constant,  $\frac{1}{4} l_x$  (  $l_x =$ ), in the positive (negative) sense with respect to the square pin lattice, forming isosceles triangular lattice. Note that the asymmetric con guration, shown in Fig.3b, in which half of the vortex chains rem ain pinned to the underlying substrate, has energy  $2T_2$  (1 2p) h, which is only slightly (i.e. by a small, second order correction in p) higher than the energy given by Eq. (12). Such an asymm etric con guration m ay becom e energetically favorable (see Ref.<sup>22;23</sup>) due to, e.g. boundary conditions which are incompatible with the even-odd chain symmetry described above.

At su ciently weak pinning, when the pinning energy becomes comparable to the di erence between the SC energies of the commensurate isosceles triangular vortex lattice with  $a_x^2 = -$ , and the incommensurate equilateral triangular lattice with  $a_x^2 = \frac{p}{3} = 2$  (A brikosov lattice), the latter ispreferable. To show this note that the energy,

 $h_1$ , of the equilateral triangular vortex lattice in the presence of incom m ensurate pin lattice is in uenced only by the average pinning potential v, so that:

$$h_4 = "_0 + v = "_0 + \frac{4}{x} pT_2$$
 (14)

C om paring this value with that obtained in Eq. (12) for the commensurate, isosceles triangular lattice,  $2T_2$  (1 p)<sup>2</sup>  $h_2$ , we nd that forp p' 25 the oating equilateral triangular lattice is the lowest energy state. This critical point can be thus identied as a transition point from pinned (commensurate) solid to a oating (incommensurate) solid state.

A second critical point exists in the strong pinning regime, i.e. at p = 1, as indicated by Eq.(13), which has no real solution at any p > 1. At this critical point the vortex lattice coincides with the square pin lattice ( i.e.  $_0 = 0$  in Eq.(13)) and the pinning energy reaches its absolute m in im um value (i.e. zero ). Since any further increase of the pinning strength above the critical value, p = 1, can not be compensated by the SC energy term s in Eq.(11), the vortex con guration rem ains xed at the square lattice structure for any p 1. Thus, with increasing values of the parameter p, the ground state vortex con guration changes continuously from a triangular lattice at  $p = p_c$ , into a square lattice at p = 1, which does not changes with further increase of the pinning strength. This continuous transform ation from a triangular lattice to a square lattice can be classi ed as a second order phase transition at p = 1.

### B. Commensurate equilibrium states at nite temperature

In the ideal vortex state at nite tem perature them al uctuations associated with the low -lying shear excitations along the principal crystallographic axis destroy the long range phase coherence of the vortex state and lead to melting of the ideal vortex lattice at a tem perature,  $T_{\rm m}$ , wellbelow the mean eld  $T_{\rm c}$ . This feature indicates an intrinsic anisotropy of the ideal vortex crystal $^{8}$ : The characteristic excitation energy for sliding vortex chains along the principal axis (denoted by x) parallel to a side of the unit cell is two orders of magnitude smaller than the SC condensation energy, and one order of magnitude smaller for uctuations along the diagonal axis (denoted by  $x^{0}$ ). For all other crystallographic orientations the shear energy is of the order of the SC condensation energy.

The nucleation of a SC crystallite can be established in such an ideal model by selecting boundary conditions which x the position of a single vortex chain with respect to the laboratory frame. As shear uctuations of parallel vortex chains diverge with the distance from the

xed chain, a SC dom ain is restricted to nucleate only around a pinned chain, its transverse size shrinking to that of a single magnetic length as the tem perature rises toward  $T_m$ . For the sake of sim plicity, we avoid here the com plication associated with the discontinuous nature of the vortex lattice melting process, which involves two principal families of easily sliding B ragg chains<sup>1</sup>, and restrict the analysis to a single family of vortex chains, i.e. that with the lowest crossover tem perature  $T_{cm}^{8}$ . A

FIG. 4: Pair correlation function between nearest Landau orbitals: (1) at strong pinning, as a function of the dimensionless inverse temperature = 4pT = T, and (2) in the triangular A brikosov vortex lattice with a single pinned chain , n = 0, as a function of  $e = T_4 = T$ 

meaningful de nition of  ${\tt T}_{\!\!cm}$   $(a_{\rm x})$  may invoke the phase correlation function,

$$C_{n^{0}:n} h e^{i('_{n^{0}} '_{n})} i$$
 (15)

between Landau orbitals,  $n^0$  and n, located near the xed chain n = 0. Thus, melting of the entire vortex lattice occurs essentially when phase correlation between the nearest neighboring chains (i.e.  $n = 1, n^0 = 2$ ) closest to the xed chain is signi cantly suppressed (e.g. by a factor of 1/2). In the p ! 0 limit we use the expression derived in Ref.(<sup>7</sup>) to nd:

$$C_{n^{0}=2;n=1}$$
 (e) '  $\frac{I_{1}$  (e)  $\frac{I_{1=2}$  (e)}{I\_{0} (e)  $\frac{I_{1=2}$  (e)  $I_{0}$  (e)

with e  $T_{\!\!4}$  =T . Here the characteristic tem perature,  $T_4$  '  $\frac{4}{1+4}$ ", with = exp( 3 =2), corresponds to interaction between the principal LOs in the equilateral triangular lattice state. Note that the crossover between the vortex solid state at zero tem perature, where e ! 1, and  $C_{n^{0}=2;n=1}$  (e) ! 1, and the vortex liquid state at high tem perature, where e ! 0, and  $C_{n^{0}=2;n=1}$  (e) ! 0, occurs at about e ' 1:5, so that  $T_{cm}$  (ax) :67T4 (see Fig. 4). This crossover tem perature is close to, though somewhat lower than the melting tem perature,  $T_m$  '  $12T_4$  '  $2:8T_2$ , predicted in Ref.(7).

The presence of the periodic pinning potential stabilizes the vortex lattice against the violent phase uctuations discussed above. This e ect is nicely demonstrated by the phase correlation function  $C_{n^0;n}$  (Eq.(15)), which controls the mean super uid density (see Eq.(2)) near the melting point. A ssum ing strong pinning, p 1, and neglecting the small GL inter-vortex-chain coupling, the correlation function can be determined from the expression:

С

$$C_{n^{0};n} \prime \frac{Q}{k} \frac{R}{Q} \frac{d_{k}}{Q} e^{i('_{n^{0}} \prime_{n})} e^{4p \cos(\kappa)}}{k_{0} d_{k} e^{4p \cos(\kappa)}}$$
(16)

U sing the identity  $r_n = \int_{k=n_0}^{n} k$ , where the value of  $n_0$  can be found from boundary conditions which in uence only the global phase of the SC order parameter, we nd that

$$I_{1} (4p)$$
<sup>j n j</sup>  
 $I_{0} (4p)$   
' exp(j n j= 8p) for 4p 1; (17)

where n  $n^0$  n. This result contrasts with the correlation function obtained in the pure state<sup>7</sup>, which has the asymptotic form

$$C_{n^{0},n} / \exp \frac{\overline{n}}{2} j n f$$
 for 1 (18)

where  $\overline{n} = \frac{n^0}{3} + \frac{2n}{3} - \frac{1}{2}$ , with the n = 0 chain being xed. As discussed above (see also Refs. $(i^{1})$ ), xing chain positions through boundary conditions is physically equivalent to introducing pinning potential into the GL functional, which is a crucial step for stabilizing the vortex lattice. The global stability of the vortex lattice in the presence of the periodic pinning potential is relational invariance of the form er correlation function, as well as by its relatively weak (sim ple exponential) decay.

To determ ine the crossover temperature from the square pin solid (SPS) to the vortex liquid we may follow the procedure described above and nd the temperature  $T_{cm}$  (a<sub>x</sub>;p) at which  $C_{n^0;n}$  in Eq.(16) for j nj= 1 is reduced by a factor of 1/2 with respect to its zero temperature ( ! 1 ) limit. This yields in the strong pinning limit, p 1 (see Fig. 4), the linear dependence

$$T_{cm}$$
 (a<sub>x</sub>;p) :86 4p<sub>2</sub> (19)

Beside its in uence on the vortex lattice melting transition, the pinning potential can change the vortex lattice structure, both continuously and discontinuously. The zero tem perature lim it was discussed in Sec.(IIIA). Above the critical value p = 1 the lateral vortex positions coincide with the pin square lattice positions, 1 = 0. For decreasing pinning strength below p = 1, the con guration of the vortex lattice deviates continuously from the square structure to a lattice with vortices shifted along chains away from the pinning centers.

Sim ilar second order SPS to TPS phase transition (as a function of p) is expected at nite temperatures. Indeed, as shown in Sec.(IIIA), the free energy functional  $f_2$  in Eq. (9) is minimized at the stationary points  $_k = _{ck}$  (1)<sup>k</sup> 0, with  $\cos 0 = p$  for p 1, and at  $_{ck} = 0$  for p 1. Thus, expanding  $f_2$  as a Taylor series in ( $_k _{ck}$ ) about its stationary points it is clear that for p 1 (when  $_{ck} = 0$ ) the expansion includes only even

powers  $_k$  (due to the symmetry of  $f_2$  with respect to  $_k$  !  $_k$ ). Thus, at any nite temperature, T , the therm almean values  $h_k\,i$  are equal to zero for p=1, implying that for pinning strengths above the critical value p=1 the mean vortex positions coincide with the square pin lattice.

### IV. PHASE DIAGRAM FOR THE LOW EST MATCHING FIELD

The results of the previous sections enable us to draw a rather clear picture of the  $V_0$  T -phase diagram, as shown in Fig. 5. In the strong pinning regime, p 1, the pinning strength is so large that the gain in com – m ensurate energy is larger than the vortex-vortex energy gain at any temperature, and so the oating solid phase is not favorable. Thus, the vortex lattice melting in this region should take place directly from the SPS to the liquid phase, as described by the asymptotic expression, Eq.(19), which is equivalent to the straight line p  $0.29T = T_2$  in the large pregime of the phase diagram.

In the smallp regime the stable phase at low tem peratures is the FS. Here the energy gain associated with creation of the closed packed equilateral triangular vortex lattice, exceeds the energy cost of the incommensurate state. This state remains stable up to a relatively high temperature T '  $2\,\mathrm{s}T_2$ , above which it melts into a vortex liquid state. The phase boundary in this region is vertical (i.e. independent of p) since it is determined by the vortex-vortex coupling and not by the pinning energy (which is a constant in the oating state).

In the low temperatures region of the phase diagram our analysis shows the existence of two phase transitions: At small pinning, increasing p above  $p_c$  25 transforms the FS discontinuously to a pin solid since the energy gain associated with the commensurate pin vortex solid exceeds the energy cost of distorting the closed packed equilateral triangular vortex lattice. The discontinuous nature of this transition is due to the fact that even in-

nitesimal deviation from a commesurate con guration rises the pinning energy by a nite amount (i.e. at least from :6v to v).

It turns out that the pin vortex crystal just above the commensurate-incommensurate transition is not a square lattice, as found by Reichhardt et al<sup>22</sup>, but a triangular one, with a unit cell which depends on the pinning strength. At T = 0 it is a parallelogram with equal base and height, which transforms continuously to a square at p = 1. Similar continuous transition from a frustrated triangular pin lattice to the SPS takes place at the critical pinning strength p = 1 at any temperature T. Interestingly, the corresponding horizontal transition line intersects the extrapolated SPS-L boundary line at T 3:44T<sub>2</sub>, p = 1, that is in the close vicinity of the intersection between the vertical FS melting line, T ' 2:8T<sub>2</sub>, and the SPS-TPS line.

It is not exactly known, however, how the FS-TPS

FIG.5:  $V_0$  T phase diagram : Solid lines - rst order phase transitions from SPS to L phase (at large pinning strength), from TPS to FS (near zero tem perature), and between FS and L phases. D ashed line - second order phase transition between partially pinned (TPS) and fully pinned (SPS) vortex crystals. The dashed-dotted line connects sm oothly between the asym ptotic SPS-L line and the low tem peratures TPS-FS line (see text for explanation).

boundary is extended beyond the zero tem perature region. It is conceivable that its high tem perature sector coincides with the low temperature sector of the SPS melting line. This is due to the fact that, at a xed value of p, the driving force for both transitions are thermal uctuations involving sliding vortex chains, which suppress the pinning energy gained in the commensurate phase (i.e. the term  $4p\cos(k)$  in Eq.(9)). In the SPS-L transitions, where the vortex-vortex interaction is relatively sm all, this suppression leads to uncorrelated vortex chains, resulting in melting. In the TPS-FS transitions, where the the vortex-vortex coupling is relatively large, the suppression of the pinning energy results in mutually correlated vortex chains, which lose correlation with the underlying pinning lattice.

An interm ediate pin solid phase of a triangular form has been also found in the London model calculation reported by Pogosov et al.<sup>23</sup>. How ever, in contrast to the G inzburg-Landau model, discussed here, they predicted the vortex con gurations shown in Fig. 3b as preferable below some critical value of the pinning potential strength. Above this value the symmetry of vortex lattice is changed discontinuously to the square symmetry of the pin lattice.

O urproposed phase diagram, show n in Fig.5, thus consists of 2 pin solid phases, a oating solid and a liquid phase, delim itted by 4 interphase boundary lines, which intersect at two nearby triple points. This result is sim ilar to the phase diagram found by Reichhardt et  $al^{22}$ , using molecular dynamics simulations. However, the intermediate TPS phase obtained in our calculation, is missing in Reichhardt et al. This seems to be due to the square boundary conditions in posed in the latter calculation. Another di erence concerns the zero temperature limit of the PS-FS line, which seems to approach p = 0 in Reichhardt et al.

### V. CONCLUSIONS

The in uence of a periodic pinning potential on the vortex state of a 2D superconductor at tem peratures well below the mean  $\;$  eld  $T_{\!c}$  has been studied within the fram ework of the GL functional integral approach. It is shown that attractive interaction of vortex cores to a commensurate pin lattice stabilizes vortex solid phases with long range positional order against violent shear uctuations along the principal crystallographic axis. Exploiting a simple analytical approach we draw a rather detailed picture of the relevant vortex state T (pinning strength-tem perature) phase diagram. р In agreem ent with previous num erical simulations<sup>22</sup>, we have found a pinned, commensurate solid phase in the strong pinning-low temperature part of the phase diagram, which melts into a vortex liquid at high temperatures, and transform s into a oating (incommensurate) solid at low temperatures. We have shown that at low temperature, sim ilar to Ref.<sup>23</sup>, there is an intermediate triangular phase, where vortices detaching from pinning centers remain strongly correlated with them. This pinned (frustrated) triangular solid transforms continuously into the fully pinned (square) solid phase at p = 1, and discontinuously to a coating solid at sm all pinning strengths. The zero temperature limit of this commensurate-incommensurate transition line occurs at a nite pinning strength ( $p = p_{2}$  25).

It is predicted that for su ciently clean samples, where random pinning is weak enough, application of an arti cial periodic pinning array with an appropriate strength would stabilize a weakly pinned vortex solid phase with long range positional order. Exploiting the SANS method to the sample under these conditions one could therefore directly detect the shear sti ness anisotropy characterizing the ideal vortex lattice.
