The density-m atrix renorm alization-group m ethod is used to study the electronic states of a twochain Hubbard model for CuO double chains of PrBa₂Cu₄O₈. We show that the model at quarter lling has the charge ordered phases with stripe-type and in-line{type patterns in the parameter space, and in-between, there appears a wide region of vanishing charge gap; the latter phase is characteristic of either Tom onaga-Luttinger liquid or a metallic state with a spin gap. We argue that the low-energy electronic state of the CuO double chains of PrBa₂Cu₄O₈ should be in the metallic state with a possibly small spin gap.

I. IN TRODUCTION

G com etrical frustration in the charge degrees of freedom of the CuO double chains of PrB a_2 Cu₄O₈ has provided an interesting opportunity for studying anom alous m etallic states realized in quasi-one-dimensional (ID) electronic conductors. Experimentally, it has been reported^{1,2,3} that the system shows metallic conductivity along the chain direction down to 2K and that it shows s insulating conductivity along the directions perpendicular to the chain above 140 K. The system may thus be regarded as a quasi-ID correlated conductor except at low temperatures. Below 140 K, the conductivity of the system shows a 2D behavior within the crystallographic a-b plane,² indicating that the coupling between the chains is not negligible.

A nom alous behaviors in $PrBa_2Cu_4O_8$ have been observed in particular in its charge degrees of freedom. A nuclear-quadrupole-resonance (NQR) experim ent⁴ showed that the tem perature dependence of the spin-lattice $(1=T_1)$ and spin-spin $(1=T_2)$ relaxations is anom alous, indicating the presence of very slow uctuations of charge carriers. A polarized optical spectrum for E k a (electric eld E parallel to the a axis) dem onstrated that the CuO₂ planes of this material maintain the charge-transfer (CT) insulating state with a CT gap of 1.4 eV, 5,6 which is typical of that of cuprates, but the spectrum for E k b (chain direction) exhibits a broad peak structure at ! > 40 meV with a very small but nonzero D rude weight (2% of the total weight). Tom onaga-Luttinger liquid (TLL) behavior was also suggested; from the power-law dependence dominating in the higher-energy part of the optical conductivity, the exponent K was estimated to be 0:24⁵ M oreover, an angle-resolved photoem ission spectroscopy (ARPES) study of Zn-doped PrBa₂Cu₄O₈ showed a power-law behavior of the spectral function near the Ferm i level, which is indicative of a TLL state, and a value K 0:24 was estim ated.^{7,8} Such a sm all value of K suggests that the long-range C oulom b interaction between charge carriers should be very strong. It was also reported that the system of the CuO double chains is near quarter lling of holes.^{5,7} A good opportunity has thus been provided for studying the anom alous charge dynam ics of strongly correlated 1D electron system s such as charge ordering (CO), charge uctuation, and charge frustration.

A few theoretical studies have so far been made on the CuO double chains of PrBa₂Cu₄O₈. Using Lanczos exact-diagonalization technique on sm all clusters, Seo and O gata⁹ studied sim ilar models and proposed possibility of the appearance of a metallic phase due to geom etrical frustration; the system sizes used were however very small, so that whether the rst charge excitation is gapped or gapless in the therm odynam ic lim it. was not clear. Zhuravlev et al.¹⁰ investigated a spinless Ferm ion model at half lling, which corresponds to a quarter-lled extended Hubbard model in the lim it of large on-site repulsion U , and found that a m etallic state is realized due to the e ect of frustration am ong Ferm ions when long-range repulsive interactions among them com pete. Am asaki et al.¹¹ calculated the optical conductivity spectrum in the mean-eld theory and showed that it agrees well with experim ent only when the stripe-type CO is present; they thereby argued that the observed anom alous optical response may be due to the presence of the stripe-type uctuations of charge carriers in the CuO double chains.

M otivated by such development in the eld, we here investigate the ground state of the extended Hubbard m odel at quarter lling, an e ective model for the CuO double chain of $PrBa_2Cu_4O_8$. An isolated double chain system is considered in this paper because to clarify its nature is essential before the dimensional crossover' is taken into account. We use the density-matrix renormalization-group (DMRG) method¹² for calculating the ground and low-energy excited states of the model, as well as its charge and spin correlation func-

tions.

W e will show that our model in its ground state has the CO phases with stripe-type and in-line(type patterns in the parameter space, and in-between, there appears a wide region of vanishing charge gap; the latter phase is characteristic of either a TLL or a metallic state with a spin gap. The spin gap remains open unless the lling deviates largely from a quarter. We will then consider possible experimental relevance of our results. We will in particular argue that the low-energy electronic state of the CuO double chains of PrBa₂Cu₄O₈ shou metallic state with a possibly small spin gap

This paper is organized as follows. In Sec. duce a single-band Hubbard model de ned on a 1D lattice for the CuO double chain of PrBa₂Cu₄O₈ and give some numerical details of the DMRG method used. In Sec. III, we present calculated results for the charge gap, phase diagram, spin correlations, charge correlations, and Luttinger parameters, and discuss anom alous properties of the liquid phase of our system. In Sec. IV, we sum – marize the results obtained and discuss their possible experimental relevance.

II. MODELAND METHOD

The structural element of PrBa₂Cu₄O₈ that we consider is the CuO double chain with unit cell Cu₂O₄,^{1,2} the geometry of which is illustrated in Fig.1 (a). The relevant orbitals on the Cu and O sites are the $3d_{x^2 y^2}$ and 2p orbitals, respectively. From the antibonding band of these two orbitals, we may extract an elective model, i.e., a single-band extended Hubbard model for low-energy electronic states of the CuO double chains (see Fig.1 (b)), where the O ions are no longer explicitly present. Such reduction of dimensionality allows us to carry out detailed numerical studies. One should also note that this two-chain Hubbard model is topologically equivalent to the single-chain Hubbard model with next-nearest-neighbor interactions as shown in Fig.1 (c).

The model we consider is thus described by the Hamiltonian

$$H = \underbrace{\begin{array}{c} X \\ H \end{array}}_{i} \begin{pmatrix} c_{1}^{y} c_{i+1} + c_{i+1}^{y} c_{i} \end{pmatrix} \\ & \underbrace{\begin{array}{c} X^{i} \\ t_{2} \end{array}}_{i} \begin{pmatrix} c_{1}^{y} c_{i+2} + c_{i+2}^{y} c_{i} \end{pmatrix} \\ & \underbrace{\begin{array}{c} X^{i} \\ + U \end{array}}_{i} \begin{pmatrix} n_{i^{*}} n_{i^{\#}} \\ n_{i^{*}} n_{i^{\#}} \end{pmatrix} \\ & + \underbrace{\begin{array}{c} X^{i} \\ V_{1} \end{array}}_{i} \begin{pmatrix} n_{i} \end{array} \\ n_{i} \end{array} \\ & \underbrace{\begin{array}{c} 1 \\ 2 \end{array}}_{i} \begin{pmatrix} n_{i+1} & 0 \end{array} \\ n_{i+2} & 0 \end{array} \\ & \underbrace{\begin{array}{c} 1 \\ 2 \end{array} \\ & \underbrace{\begin{array}{c} 1 \\ 2 \end{array}}_{i} \end{pmatrix} \\ & \underbrace{\begin{array}{c} 1 \\ 2 \end{array} \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ & \underbrace{\begin{array}{c} 1 \\ 2 \end{array} \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ & \underbrace{\end{array} \end{array} \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ & \underbrace{\end{array} \end{array} \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ \\ & \underbrace{\end{array} \end{array} \\ & \underbrace{\begin{array}{c} 1 \end{array} \\ \\ & \underbrace{\end{array} \end{array} \\ \\ & \underbrace{\end{array} \end{array} \end{array}$$
 \\

where we use the notations for the 1D chain de ned in Fig.1(c). c_i^v (c_i) is the creation (annihilation) operator of a hole with spin (= ";#) at site i and $n_i = c_i^v c_i$ is

FIG.1: (a) Schem atic representation of the lattice structure of the CuO double chain. The solid circles represent Cu $(d_{x^2 \ y^2})$ orbitals and the open circles represent O (p) orbitals. (b) The corresponding two-chain Hubbard model. (c) G eom etrically equivalent single-chain Hubbard model.

the number operator. t_1 and V_1 are the nearest-neighbor hopping integral and Coulom bic repulsion, respectively, which are for the zigzag bonds connecting two chains of the two-chain model (see Fig. 1 (b)). t_2 and V_2 are those for the next-nearest-neighbor bonds, which are for the chain bonds of the two-chain model. We assume t₁ t2 because of the bonding angle m in im izing the overlap the Cu $3d_{x^2 y^2}$ and O 2p wave functions for the hopping param eter t_1 ; in the following, we use the value $t_1 = t_2 = 0$:1 unless otherwise stated, by con ming that the sign of t_1 does not change the results. We assume a value of the on-site C oulom b interaction U as $U=t_2 = 20$, which is som ew hat larger than a typical value for cuprate m aterials; by using this value, however, we can investigate interesting features of our model with a wide range of V1 and V_2 . We believe that this choice does not change the essential features of our results. The lling of holes in 0:5^{5,7};we the CuO double chains is reported to be n therefore restrict ourselves to the case at quarter lling unless otherwise indicated, i.e., $n = \frac{1}{2}$ corresponding to a density of one hole per two Cu sites. Note that the repulsions V_1 and V_2 are frustrating interactions for the charge degrees of freedom of the system in the sense that two holes can choose to sit on two of the three sites of a triangle of the lattice in mutually competing energy scales V_1 and V_2 (see Fig. 1(b)). If we assume the intersite Coulomb repulsions to be inversely proportional to the intersite distance, we have the relation $V_1 = 2V_2$, which is not far from the line $V_1 = 2V_2$ where the two repulsions V_1 and V_2 exactly compete at $t_1 = t_2 = 0$.

We use the DMRG method,¹² a powerful numerical technique for a variety of 1D systems, whereby we can obtain very accurate ground-state energies and expectation values for very large nite-size systems. We study the chains with up to 128 sites. The open-end boundary

conditions are used; when we calculate local quantities, they are actually the ones averaged over the chain and when we show correlation functions, they are the ones m easured from the midpoint of the chain. We use up to m = 2000 density m atrix eigenstates to build the DMRG basis. One needs to keep relatively large values of m to obtain su cient accuracies in our system because the long-range hopping term increases the truncation error rapidly; this is in particular the case when $t_1 \prime 0$. Extrapolating the DMRG ground-state energies calculated for di erent m values to an energy for vanishing discarded weight, 13 we obtain the ground state energy and excitation gap which are accurate to parts in 10 3 t₂. A lthough the largest source of errors in our calculations are nite size e ects, we are able to extrapolate a num ber of gap values m easured for di erent system sizes to a value for an in nite system-size chain.

In the following, we rst present calculated results for the charge gap in order to show that the geom etrical frustration indeed induces the metal-insulator (M I) phase transition; the ground-state phase diagram is shown in the parameter space of the inter-site C oulomb interactions. We then present calculated results for the density distributions, spin-spin correlation functions, charge velocities, and the density-density correlation functions, in order to discuss possible anom alous behaviors of the metallic phase.

III. RESULTS OF CALCULATION

A. Charge gap

The charge gap of an L-site chain is de ned by

$${}_{\rm C}({\rm L}) = \frac{1}{2} {\rm E}_{0} ({\rm N}_{*} + 1; {\rm N}_{\#} + 1; {\rm L})$$

+ {\rm E}_{0} ({\rm N}_{*} - 1; {\rm N}_{\#} - 1; {\rm L}) 2 {\rm E}_{0} ({\rm N}_{*}; {\rm N}_{\#}; {\rm L}) (2)

where E_0 (N "; N #; L) denotes the ground-state energy of a chain of length L with N " spin-up holes and N # spindown holes. In Fig. 2 (a), we show calculated results for

 $_{\rm c}$ (L)=t₂ at V₁=t₂ = 5 for several V₂=t₂ values and system sizes L up to 80 sites. We nd that $_{\rm c}$ (L) decreases m onotonically with increasing L, so that we can extrapolate $_{\rm c}$ (L) to the therm odynam ic limit system atically by performing the least-square t of $_{\rm c}$ (L) to a second-order polynomial in 1=L. The extrapolated results $_{\rm c}$ =t₂ ($_{\rm c}$ (L ! 1)=t₂) are shown in Fig.2 (b). It is evident that for both sm all V₂=t₂ < 1:56 and large V₂=t₂ > 5:95, $_{\rm c}$ =t₂ is nite, i.e., the system is insulating, and in a wide range of V₂=t₂, i.e., 1:56 < V₂=t₂ < 5:95, $_{\rm c}$ =t₂ vanishes within the accuracy of the extrapolation. We not similar situations for other values of V₁=t₂ as well, which demonstrates that a stable m etallic phase indeed exists between two insulating phases.

W hen $t_1 = t_2 = 0$, we readily nd from a total-energy calculation that there are two ordered phases, of which

FIG.2: Charge gap in the extended H ubbard m odel [Eq.(1)] at quarter lling for $V_1=t_2 = 5$ and $t_1=t_2 = 0.1$. (a) $_c$ (L)= t_2 calculated as a function of the inverse system size 1=L for $V_2=t_2 = 0$ (lled circles), 1 (open circles), 2 (lled triangles), 6 (open triangles), 8 (lled squares), and 10 (open squares). D ashed lines are the quadratic ts in 1=L. (b) $V_2=t_2$ dependence of $_c=t_2$ in the therm odynamic lim it L ! 1. The circles show the results obtained by extrapolation of the DM RG data in (a). The dashed lines are a guide to the eye.

the phase boundary locates on a $V_1 = 2V_2$ line. The phase in the $V_1 > 2V_2$ region is characterized by an in-line CO, i.e., all the holes locate on one of the two chains of the two-chain model, whereas the phase in the $V_1 < 2V_2$ region is characterized by a stripe-type CO, i.e., holes locate alternately on sites of both of the two chains form ing a stripe-like pattern along the chain direction. The stripe-type CO corresponds to the $2k_F$ charge-densitywave (CDW) state and the in-line CO corresponds to the $4k_F$ -CDW in the single-chain notation of Fig.1 (c). Note that, if we assume the intersite Coulomb repulsion to be inversely proportional to the intersite distance, we have $V_1 = \frac{1}{2}V_2$ and hence the stripe-type CO should be realized, but if we assume a faster decay of the intersite repulsion due to the e ect of screening, the energies of the two phases can be more com parable.

By making t_1 and t_2 nite to introduce quantum uctuations, there appears the metallic state between these two insulating phases, where the two intersite repulsions

FIG.3: Ground-state phase diagram of the model [Eq.(1)] in the parameter space of the intersite C oulom b interactions. The values $t_1 = 0.1t_2$ and $U = 20t_2$ are assumed. The open (solid) circles indicate the phase boundary between the $2k_F - CDW$ ($4k_F - CDW$) and metallic states, at which the calculated charge gap $_c$ vanishes. The solid line corresponds to $V_2 = t_2 = V_1 = (2t_2)$. Details of the metallic phase are discussed in Sec. III E.

 V_1 and V_2 are mutually competing, as we have shown above. The ground-state phase diagram of our model (see Sec. III E for detailed discussion) therefore includes three phases in the parameter space as shown in Fig. 3; (i) the insulating phase with the $4k_{\rm F}$ -CDW (or in-line CO) realized when V_1 is large, (ii) the insulating phase with the $2k_{\rm F}$ -CDW (or stripe-type CO) realized when V_2 is large, and (iii) the metallic phase in-between. These three phases are discussed further in the following subsections.

B. Charge ordering

Let us rst consider the three phases from the viewpoint of ordering of charge degrees of freedom . We rst of all note that the CO is a state with a broken translational sym m etry; there are two degenerate ground states, and in the open-end boundary conditions we use here, one of the two ground states is picked out by initial conditions of the calculation. The CO state is thus directly observable in our calculations.

For small values of $V_2 = t_2$ ($V_1 = 2t_2$ 0 (t_2)), the effect of $V_1 = t_2$ dominates and leads to a CO with wave vector $q = 4k_F$ in the single-chain notation (which corresponds to the in-line{type CO in the two-chain notation); namely, the ground state of the system is dominated by con gurations such as

...01010101010...,

where \1" stands for a site supporting one hole and \0" stands for an empty site. F ig. 4 (a) shows an example of the Friedel oscillation appeared in the density distribution h_i in the nite-size system of L = 128.0 ne can see the $4k_F$ -CDW behavior clearly. The oscillations persist at the center of the chain and the di erence between the

FIG.4: Calculated hole densities at site i for (a) the $4k_F - CDW$ (or in-line{type CO) at $V_2 = t_2 = 0$ (crosses) and 1 (circles), (b) $2k_F - CDW$ (or stripe-type CO) at $V_2 = t_2 = 6$ (circles) and 8 (crosses), and (c) uniform metallic phase at $V_2 = t_2 = 2$. We assume $V_1 = t_2 = 5$ and use the system of L = 128. Results for central 40 sites are shown in (a) and (b).

results for $V_2 = t_2 = 0$ and 1 is hardly visible. We calculate $hn_i i$ for several chain lengths and con rm that the system size with L = 128 is su ciently large and the nite-size e ect is negligible. We also calculate the density-density correlation function N (1) de ned as

$$N (l) = hn_{i+l}n_{i}i \quad hn_{i+l}ihn_{i}i; \qquad (3)$$

with $n_{i} = n_{i^{\prime\prime}} + n_{i\#}$ and nd that N (l) tends to a nonzero constant value as the intersite distance l increases: e.g., N (l! 1) 10⁷ at V_{1} =t₂ = 5 and V_{2} =t₂ = 1. This indicates the presence of the long-range ordered $4k_{F}$ -CDW state.

At $V_2 = t_2 = 0$ where the $4k_F - C D W$ is stabilized, most of the charges are located on one of the two chains of the two-chain m odel although there are some charges on the other chain due to quantum uctuation by a small value

of $t_1=t_2$; at $t_1=t_2 = 0$, the charges are disproportionated on one of the chains completely. W ith increasing $V_2=t_2$, the charge gap decreases rapidly (see Fig. 2 (b)), but the $4k_F$ -CDW correlation is hardly suppressed until reaching a sharp decline occurred around the M I transition point. This transition is of the second-order due to the presence of a sm all value of t_1 ; if $t_1 = 0$, this transition should be of the rst-order. These results suggest that at $V_2=t_2 < 1.56$ and $V_1=t_2 = 5$ the system m ay be regarded as a half-led extended H ubbard m odel since m ost of the charges are disproportionated. W e note that, in the case of $t_1 = 1$ and $t_2 = 0$, the suppression of $4k_F$ -CDW correlation by V_2 has been suggested in the weak-coupling renorm alization-group study.¹⁴

For large values of $V_2=t_2$ ($> V_1=2t_2 + O(t_1)$), $V_2=t_2$ enhances the $2k_F$ -CDW uctuations and induces a CDW with wave vector $q = 2k_F$ (or a stripe-type CO in the twochain notation). The ground-state wave functions have dom inant con gurations of the type

...011001100110...

where we use the same notations as above. Fig. 4(b) shows an example of the Friedel oscillation appeared in the density distribution h_1i in the nite-size system of L = 128. The $2k_F$ -CDW behavior is clearly seen. The calculated values of N (l) tends to a nonzero constant as the intersite distance lincreases: e.g., N (l! 1) 10⁸ at V_1 =t₂ = 5 and V_2 =t₂ = 8. This indicates the presence of long-range ordered $2k_F$ -CDW state.

W hen $V_2=t_2$ is much larger than $V_1=t_2$, $2k_F - CDW$ (or stripe-type CO) is stabilized, i.e., in the single-chain notation, two occupied sites and two empty sites com e altemately. As shown in the next subsection, two spins on the neighboring two sites form a spin-singlet pair. As $V_2=t_2$ decreases, c decreases in proportion to $V_2=t_2$, and its behavior is sim ilar to that of the model without hybridization ($t_1 = t_2 = 0$); i.e., $c = 2(V_2)$ $V_{2}^{c;2k_{\rm F}}$) around the M I transition point $V_2^{c;2k_F}$. This suggests that the charges disproportionate alm ost com pletely as soon as the charge gap opens. It can also be veri ed by slight reduction of the amplitude of the 2k_F -CDW oscillation that occurs when $V_2 = t_2$ decreases. This means that the e ect of $V_1 = t_2$ directly weakens the e ect of $V_2 = t_2$ and melts the $2k_F$ -CDW state. This situation is similar to the M I transition of the quarter-lled extended Hubbard model. The transition is of the second order for $t_2 > 0$; it is of the rst order only at $t_2 = 0$.

For interm ediate values of $V_2=t_2$ (or around $V_1 = 2V_2$), the system is in the m etallic state. As expected, the am – plitude of the Friedeloscillation is quite sm all as show n in F ig. 4 (c), which should vanish at the center of the chain when L ! 1 . In this phase, competition of two incom – patible uctuations, i.e., the $2k_F$ and $4k_F$ (or stripe-type and in-line{type}) charge uctuations, prohibit the system from forming CO states. However, it is useful to know what is the dom inant correlation; here, we exam ine the long distance behavior of the density-density correlations N (l), in particular its period of oscillation. We thus nd

FIG. 5: Order parameters $_{4k_{\rm F}}$ and $_{2k_{\rm F}}$ as a function of $V_2=t_2$ for various system sizes at $V_1=t_2$ = 1. The led (open) symbols are the results for $_{4k_{\rm F}}$ ($_{2k_{\rm F}}$). The up-triangles, circles, and down-triangles denote the results for L = 16, 48, and 80, respectively.

that the $2k_F$ CO correlation is dom inant for $2V_2 > V_1$ and the $4k_F$ CO correlation is dom inant for $2V_2 < V_1$, as will be discussed further in Sec. III D.

In order to explain relationship between the M I transition and CO form ation, we introduce the order param – eters de ned as

$$_{4k_{\rm F}} = \frac{1}{L_{\rm e}} \sum_{j}^{X} e^{i4k_{\rm F} r_{\rm j}} n_{\rm j} = \frac{1}{L_{\rm e}} \sum_{j}^{X} (1)^{j} n_{\rm j} \qquad (4)$$

for the $4k_{\rm F}$ -C DW $\,$ and $\,$

$$_{2k_{\rm F}} = \frac{1}{L_{\rm e}} \sum_{j}^{\rm X} e^{i2k_{\rm F} r_{\rm j}} n_{\rm j} = \frac{1}{L_{\rm e}} \sum_{j}^{\rm X} \cos \frac{1}{2} j n_{\rm j};$$
 (5)

for the $2k_F$ -CDW . Here, the sum is taken over central L_e (= L a) sites excluding a=2 sites at both ends of the system in order to eliminate edge e ects; here we take a '8 12.

The obtained results at $V_1 = t_2 = 5$ as a function of $V_2 = t_2$ are shown in Fig. 5 for a number of system sizes. We nd that as the system size increases the slopes of the curves around the critical points becom e steeper and that the result at L = 48 is nearly equal to the result at L = 80. Thus, the situation in the therm odynam ic lim it may well be expected except near the critical point where the size e ect is not negligible. Let us focus on the $2k_F - CDW$ transition at $V_2=t_2$ ' 5:95. Then, $2k_F$ shows a sharp developm ent around $V_2=t_2$ 5, which is rather sm aller than the value of $V_2^{c;2k_F} = t_2$ show n in Fig. 2 (b). How ever, in them odynam ic lim it, this turning point should agree with $V_2^{c;2k_F} = t_2$, and the transition seems to be still continuous. W e note that the transition becom es sharper for $larger V_1 = t_2$ (or sm aller t_2) values and is of the rst-order in the lim it V_2 ! 1 (or t_2 ! 0). A similar interpretation can also be given to the $4k_F - CDW$ transition.

FIG.6: (a) Spin-spin correlation function S (l) as de ned in Eq. (6) at $V_2=t_2 = 0$ (crosses) and 1 (circles) with $V_1=t_2 = 5$. The distance l is measured along the t_1 -chain in units of the interval between two sites. The log-log plot in the inset show s that the power-law decay of correlations. (b) S (l) at $V_2=t_2 = 8$ (circles) and 10 (crosses) with $V_1=t_2 = 5$. The sem ilog plot in the inset show s the exponential decay of correlations.

C. Spin correlations

In order to study the spin degrees of freedom of the system, we now calculate the spin-spin correlation function de ned by

$$S(1) = S_{1}^{z}S_{1+1}^{z}$$
; (6)

with $S_{i}^{z} = (n_{i''} - n_{i\#}) = 2$.

Let us rst discuss the 4k_F -CDW phase (or in-line CO phase in the two-chain notation). Fig. 6(a) shows the spin-spin correlation functions calculated at $V_2 = t_2 = 0$ and 1 with $V_1 = t_2 = 5$ for the system of L = 128. The site i in Eq. (6) is xed at the middle of the chain. One can clearly nd the antiferrom agnetic correlations between neighboring spins localized on one of the two-chains of the two-chain model, i.e., formation of the $2k_F$ spindensity-wave (SDW). One also notes that, because the charge uctuations through the zigzag bonds connecting two chains are nearly zero due to a very small value of $t_1 = t_2$, no spin correlations between two chains of the twochain modelare seen. As shown in the inset of Fig. 6(a), the spin-spin correlations decay as a power law, sim ilar to those for the 1D Heisenberg chain, which depends very little on $V_2 = t_2$ unless the $4k_F - CDW$ state is broken. This

FIG.7: Spin gap $_{s}=t_{2}$ as a function of $t_{1}=t_{2}$ for $V_{2}=t_{2} = 0$ (crosses), 5 (squares), and 8 (open circles) at $V_{1}=t_{2} = 5$ in the therm odynam ic lim it L ! 1. The dashed line is $_{s} = 0.5 (t_{1}=t_{2})^{2}$

suggests that the system may be well described as the 1D Heisenberg chain combined with an empty chain, as the in-line CO state may suggest.

Now let us turn to the correlations in the $2k_{\rm F}$ -CDW phase (or the stripe-type CO phase in the two-chain notation). Fig. 6(b) show the spin-spin correlation functions for V_2 =t_2 = 8 and 10 at V_1 =t_2 = 5. The behavior of S (l) for l = 4n (n = 0;1;2;) shows the antiferrom agnetic correlations. This corresponds to the $2k_{\rm F}$ -SDW state of one of the two chains at quarter lling. We nd simultaneously that there appears an SDW on the other chain; the phase of the SDW is shifted by 3 =4 from the other SDW. It might be as if the two SDW states coexist.

Because a sign of S (4n) is opposite to those of S (4n 1), the spins on the neighboring two sites should be opposite. The sem ilog plot in the inset of Fig. 6 (b) shows the exponential decay of the spin-spin correlations. The correlation lengths are 4:17 and 3:57 for $V_2 = t_2 = 8$ and 10, respectively. S (4n 1) and S (4n 3), which correspond to the spin-spin correlations between two t_2 -chains, decay with the same correlation length as S (4n). These behavior are sim ilar to the case of the two-leg H eisenberg (and half-led Hubbard) ladder system . The correlation length is close to that for the two-leg isotropic H eisenberg 3:19¹⁵ This means the e ective hopping besystem tween the next-nearest-neighbor sites along a t₂-chain, ie., sites i and i+ 4, is of the order of t1. Furtherm ore, we have found that S (1) decays exponentially even in m etallic regime near the $4k_F - CDW$ insulating phase.

From the exponential decay of the spin-spin correlations, we expect the system to be in a gapped spin-liquid state. In order to con mm it, we have calculated the spin gap de ned by

$$_{s}(L) = E_{0}(N_{*}+1;N_{*}-1;L) E_{0}(N_{*}-1;N_{*}+1;L)$$
 (7)

for an L-site chain. In Fig. 7, we show the extrapolated values $_{\rm S}$ (= $_{\rm S}$ (L ! 1)) at V₁=t₂ = 5 for V₂=t₂ = 0 (4k_F-CDW phase), 5 (m etallic phase), and 8 (2k_F-CDW phase). In the 4k_F-CDW phase, we nd that $_{\rm S}$ is always zero, which is quite natural since the system can

(13)

V ₂ =t ₂	К	V _c
2	0.55	0.295
3	1.25	0.738
4	0.88	0.401
5	0.27	< 0:01

even for nite interactions, one may expect that the system at low energies should behave as a two-band model.¹⁷ In the two-band model, it is known that only $4k_F$ -CDW and d-wave superconducting (SCd) correlations decay as power laws, and all other correlations decay exponentially; i.e., either SCd correlation or $4k_F$ -CDW correlation dom inates for both weak and strong interactions.¹⁸ The $4k_F$ -CDW correlation and SCd correlation at large distances can be written like

N (1)
$$\cos(4k_{\rm F} 1) 1^{2K}$$
; (11)

and

with

h $_{i+1}^{y}$ $_{i}$ $_{1-2K}^{1-2K}$; (12)

 $_{i} = \frac{1}{P-2} (C_{i} C_{i+1} G_{i+1});$

respectively.

In Fig.8, we show the density-density correlation function N (l) de ned in Eq. (3) on a log-log scale in order to estim ate the exponent of the decay. At large distances (l > 10), the envelope of the correlation is consistent with a straight line on the log-log scale and therefore one m ay say that it decays as a power law. Fitting the decay to Eq. (11) allows us to determ ine the value of K although the tting includes some errors due to Friedel oscillations in the data. The values obtained are given in Table I, which would be of su cient accuracy when we consider available experim ental results.

 $AtV_2=t_2$ ' 2:5, N (1) decays most rapidly and K is the largest. This means that the long-range interactions are e ectively weakened since V_1 and V_2 are canceled with each other. Such a situation seem s to be realized around $V_2=t_2 = V_1=(2t_2)$. Generally, long-range Coulomb repulsions suppress the value of K . In our results, Kdecreases when the values of V_1 and V_2 deviate from the relation $V_1 = 2V_2$, whereby the elective interaction strength increases. Now we note that the 2k_F -CDW transition occurs when K = 1=4, which m ay be understood if we suppose that two independent t_2 -chains at quarter lling undergo a $4k_F' - CDW$ transition. On the other hand, the $4k_F - CDW$ transition occurs when K = 1=2. This may be understood if we assume that the system consists of a half-lled chain and an empty chain in the 4k_F-CDW phase.

FIG.8: Density-density correlation function N (l) de ned in Eq.(3) plotted on a log-log scale. The results are for $V_2=t_2=3$ (led triangles), 4 (open squares), and 6 (led circles) at $V_1=t_2=5$, with L = 128. The distance l is measured along the 1D chain of Fig.1(c) in units of the interval between two sites.

be presumed to be a 1D Heisenberg model as mentioned above. In the $2k_F$ -CDW phase, we not that the spin gap is always nite except at $t_1 = 0$ and the size of the gap can be scaled with t_1^2 , i.e.,

$$\frac{s}{t_2}$$
, $\frac{1}{2}$, $\frac{t_1}{t_2}$, (8)

as expected from the assumption that the neighboring two sites couple with the exchange interaction J.B ecause the spin gap for a two-leg isotropic H eisenberg ladder is $_{\rm s}$ J=2¹⁵, we can estimate the elective exchange interaction as

$$\frac{J}{t_2} = \frac{t_1}{t_2}^2 : \qquad (9)$$

As for the m etallic phase, $_{\rm s}$ goes through a maximum at a nite value of $t_1 = t_2$ because an increase of $t_1 = t_2$ leads to an increase in the elective exchange coupling, as well as a decrease in the $2k_{\rm F}$ -CDW $\,$ uctuations. This behavior reminds us of the spin gap of the two-leg CuO ladder m aterials where the gap behaves similarly as a function of the energy di erence between the O and Cu sites. 16

D. Luttinger param eter

Let us calculate the Luttinger parameter K which enables one to know competitions among correlations in the m etallic phase. The H am iltonian Eq. (1) has the energy dispersion relation

$$''(k) = 2t_{\pm} \cos k \quad 2t_{\pm} \cos 2k:$$
 (10)

in the absence of interaction. If t_1 t_2 and $n = \frac{1}{2}$, the Ferm isurface has four Ferm ipoints k_{F_1} and k_{F_2} , and

8

W e note that the SC d correlations decay m ore rapidly than the $4k_F$ -CDW correlations in the whole m etallic phase even if K > 1. The inverse relationship of exponents predicted by a bosonization picture^{19,20} seems not to be preserved. The same e situation was also seen for the two-leg H ubbard ladder,²¹ w here it is known that enhancement of the SC d correlation is not adequately observed due to the nite-size e ect, i.e., the widely separated energy levels near the Fermi energy.

The slopes at 1=L ! 0 in Fig.2(a) yield $v_c{=}(2K)$, from which we can estim ate the charge velocity $v_c{.}$ W e nd that v_c goes through a maximum around $V_2{=}t_2$ = 2.5 where the electrons can move almost freely despite the e ect of double occupancy on a site. We note that the calculated very small charge velocities near the $2k_F$ – and $4k_F$ -CDW states (see Table I) may suggest heavy-Ferm ionic features, for which the geom etrical frustration may play a crucial role.^{22,23,24}

E. Phase diagram

In Fig. 3 we show the ground-state phase diagram of the system in the parameter space of the intersite Coulomb interactions $V_1 = t_2$ and $V_2 = t_2$. The phases are distinguished by the presence of a gap for spin and/or charge excitations. Naturally, a CDW state is expected if either $V_1 = t_2$ or $V_2 = t_2$ is large. The ground state of the 2k_F-CDW (4k_F-CDW) phase is a CO state with (without) spin gap and always insulating. Then, if both $V_1 = t_2$ and $V_2 = t_2$ are su ciently sm allor the elective long-range Coulomb interaction is weak due to frustration between two interactions, the system may be in a metallic phase. The metallic phases can be divided into two regions. One is the spin-gapped-liquid (SGL) phase where there is a nite spin gap but no charge gap. Here, the system is under the in uence of $2k_F - CDW$ transition and the $2k_F -$ CDW uctuation is dom inant. A nother is the TLL phase where neither spin gap nor charge gap is present and the $4k_{\rm F}$ -CDW uctuation is dom inant.

For a lucid discussion, let us now assume the case $U=t_2 \ ! \ 1$ and consider some limiting cases. When $V_1=t_2 = 0$, the $2k_F$ -CDW transition occurs at $V_2=t_2$ ' 2:3. If the system can be regarded as two separate t_2 -chains due to very small $t_1=t_2$, this transition would be equivalent to the $4k_F$ -CDW transition of the quarter-

led spinless Hubbard chain with the nearest-neighbor hopping t_2 and the next-nearest-neighbor C oulom b repulsion V_2 , where the critical value of $V_2=t_2$ is expected to be 2, which is consistent with our results.

When $V_2=t_2 = 0$, the $4k_F$ -CDW transition occurs around $V_2=t_2$ ' 2. We can estimate this value from comparison between the energies of the metallic and insulating solutions. First, the metallic solution may be obtained as follows. Consider the system consisting of two independent quarter-lled t_2 -chains. Then, if we assume the Coulomb repulsion between the t_2 -chains, the total ground-state energy m ay roughly be evaluated as

$$2E_{0}^{t_{2}}(n = \frac{1}{2}) + \frac{V_{1}}{4}L: \qquad (14)$$

Here $E_0^{t_2}$ (n = $\frac{1}{2}$) is the ground-state energy of a spinless-Ferm ion model de ned on a single chain at quarter lling with the nearest-neighborhopping t_2 , and V_1 =4 is the average C oulom b interaction. N ext, the insulating solution may readily be obtained because it corresponds to the $4k_F$ -CDW state, i.e., one of the t_2 -chains is at half 11ing and another t_2 -chain is empty, whereby we obtain the ground-state energy to be almost zero. Hence, the condition for emergence of the $4k_F - CDW$ state is that the value of Eq. (14) is larger than zero. If we use an estimation $E_0^{t_2}$ (n = $\frac{1}{2}$) ' 0:25th m ade from the Lieb-W u equations, r^{25} the critical interaction strength can be obtained as $V_1 = t_2 ' 2$. We should note that, because we have used a sm allbut nite value of $t_1 = t_2$, the actual critical values of the interactions calculated are rather larger than the above estimation.

Next, we turn to the case where both $V_1 = t_2$ and $V_2 = t_2$ are nonzero. Naturally, the system is metallic for sm all V_1 and V_2 (< 0 (t₂)), and the metallic phase becomes narrower as the long-range Coulom b interactions increase along the line $V_2=t_2 = V_1=(2t_2)$. For very large values of V_1 and V_2 , the boundary between the $2k_F - CDW$ (the $4k_F$ -CDW) and the SGL (TLL) phases becomes parallel to the line $V_2=t_2 = V_1=(2t_2)$, and the distance between the two phases remains to be of the order of t_2 (t_1) even in the lim it of V_1 ! 1 and V_2 ! 1. Even if there is no hybridization, i.e., $t_1 = t_2 = 0$, the charge mode is gapless on the line $V_2=t_2 = V_1=(2t_2)$. This means that the e ects of V_1 and V_2 are precisely cancelled out on that line. Now, if nite values of t_1 and/or t_2 are introduced, the energy gain due to moving holes expands the width of the line. We point out that the width of metallic regime depends on the di erence V between two repulsive interactions V_1 and V_2 ($V = V_1 - V_2$), rather than the values V_1 and V_2 them selves. To check this notion, we calculate the critical strength of $V_2 = t_2$ for very large value of $V_1 = t_2$. The critical interaction strengths for the $4k_F$ -CDW and 2k_F-CDW transitions are obtained respectively as follow s: $V_2 = t_2$ 249:5 and 253:5 for $V_1 = t_2 = 500$, and 499:5 and 503:5, where we assume $V_1 = t_2 = 1000$ $V_2 = t_2$ and $U = t_2 = 4000$. If $t_1 = 0$ ($t_2 = 0$), the boundary of the $2k_F - CDW$ (the $4k_F - CDW$) phase should be asymptotic to the line $V_2 = t_2 = V_1 = (2t_2)$.

IV. SUMMARY AND DISCUSSION

U sing the DM RG m ethod, we have studied the electronic states of a two-chain Hubbard m odel at quarter lling that m odels the low energy electronic states of the CuO double chains of PrBa₂Cu₄O₈. We have show n that the m odel has the CO phases with the stripe-type and in-line{type patterns in the parameter space and between

FIG.9: Normalized optical conductivity on a log-log scale. Parameter values used for calculation are: $U=t_2 = 20$, $V_1=t_2 = 2$, $V_2=t_2 = 5$, L = 32, and n = 0.46875. Finite broadening width $= 0.4t_2$ is introduced. The solid line shows a tting to the form (!)/!. 1.5 is found.

the two CO phases there appears a wide region of vanishing charge gap, which is due to geom etrical frustration of the long-range Coulom b interactions. The phase diagram of our model consists of four phases characteristic of (i) the stripe-type CO (or $2k_F$ -CDW), (ii) in-line(type CO (or $4k_F$ -CDW), (iii) Tom onaga-Luttinger liquid, and (iv) spin-gapped liquid. For the liquid phases, we have suggested possible em ergence of a heavy-Fem ion-like behavior, which can occur near the region of the m etal-insulator phase boundary.

Finally, let us discuss consistency between our numerical results and available experimental data on PrBa₂Cu₄O₈. Com parable experimental features are the appearance of the TLL behaviors and estimation of the $0:24^{5,7,8}$ W e can explain such a small value value K of K only by assuming that the system is in the $2k_F$ -CDW state or in the SGL state near the $2k_{\rm F}$ -CDW phase boundary. In these two phases of our phase diagram, how ever, a sm all but nite spin gap clearly exists except at $t_1 = 0$. We have also con med that the spin gap remains open even if the system is doped slightly away from quarter lling. Thus, the phase is not TLL unless $t_1 = 0$, which is apparently not consistent with experiment. One possibility for reconciliation may be that the CuO double chain system has a very small value of

t1, so that experiments performed with nite resolution cannot detect the e ects of the spin gap. Another possibility is that the optical and ARPES spectra observed in relatively high energies are insensitive to the opening of the spin gap. To dem onstrate this, we have calculated the optical conductivity of our model with the dynam icalDMRG method²⁶ and con med that the shape of the higher energy part (h! > c) of the conductivity does not depend on the existence of sm all values of t_1 . In Fig. 9, we show an example of the t_1 -dependence of the optical conductivity calculated for a possible set of parameters. We nd that the spectra for $t_1 = t_2 = 0$ and 0:1 are alm ost the same and the power-law decay can be seen at h! > c. From a t of the results to the form

(!) / ! , we estim ate the value 1:5, which corresponds to K 0:22. This value is very close to the value obtained experim entally. Here we point out that the long-range CDW ground state cannot reproduce the experimental spectrum but a smallhole doping of only a few % changes the shape of spectrum largely leading to the power-law decay of the spectra at high energies. We therefore suggest that the actual material is located in the SGL phase near the $2k_F - CDW$ phase or in the $2k_F -$ CDW phase with slight doping. We also want to suggest that, if the NMR Knight-shift measurement is made on the spin degrees of freedom of the double-chain Cu (1) site of PrB a_2 C u_4 O $_8$, one should be able to detect anom alous behaviors associated with the spin-singlet form ation due to the stripe-type uctuation of charge carriers.

A cknow ledgm ents

W e would like to thank E. Jeckelm ann for the use of the DMRG code originally written by him and useful discussions on the num erical techniques. W e also would like to thank S. Fujiyama, H. Ikuta, Y. Itoh, and K. Takenaka for enlightening discussion on the experim ental aspects. This work was supported in part by Grants-in-A id for Scienti cR esearch (N os.11640335 and 12046216) from the M inistry of E ducation, Culture, Sports, Science, and Technology of Japan. A part of com putations was carried out at the com puter centers of the Institute for M olecular Science, O kazaki, and the Institute for Solid State P hysics, U niversity of Tokyo.
