Damped nite-tim e-singularity driven by noise

H ans C. Fogedby Institute of Physics and Astronomy, University of Aarhus, DK-8000, Aarhus C, Denmark and NORDITA, Blegdam svej 17, DK-2100, Copenhagen , Denmark (Dated: April 14, 2024)

We consider the combined in uence of linear damping and noise on a dynamical nite-timesingularity model for a single degree of freedom. We nd that the noise electively resolves the nite-time-singularity and replaces it by a rst-passage-time or absorbing state distribution with a peak at the singularity and a long time tail. The damping introduces a characteristic cross-over time. In the early time regime the probability distribution and rst-passage-time distribution show a power law behavior with scaling exponent depending on the ratio of the non linear coupling strength to the noise strength. In the late time regime the behavior is controlled by the damping. The study m ight be of relevance in the context of hydrodynamics on a nanom eter scale, in material physics, and in biophysics.

I. IN TRODUCTION

The in uence of noise on the behavior of nonlinear dynam ical system is a recurrent them e in modern statistical physics [1]. In a particular class of systems the nonlinear character gives rise to nite-time-singularities, that is solutions which cease to be valid beyond a particular nite time span. One encounters nite-time-singularities in stellar structure, turbulent ow, and bacterial grow th [2, 3, 4]. The phenom enon is also seen in Euler ows and in free-surface-ows [5, 6]. Finally, nite-time-singularities are encountered in modelling in econophysics, geophysics, and material physics [7, 8, 9, 10, 11].

In the context of hydrodynam ical ow on a nanoscale [12], where m icroscopic degrees of freedom com e into play, it is a relevant issue how noise in uences the hydrodynam ical behavior near a nite-time-singularity. Leaving aside the issue of the detailed reduction of the hydrodynam ical equations to a nanoscale and the in uence of noise on this scale to further study, we assume in the present context that a single variable or \reaction coordinate" e ectively captures the interplay between the singularity and the noise.

In a recent paper [13] we investigated a simple generic model system with one degree of freedom governed by a nonlinear Langevin equation driven by Gaussian white noise,

$$\frac{dx}{dt} = \frac{1}{2xj^{+}} + ; \quad h \quad i(t) = (t):$$
(1.1)

The model is characterized by the coupling parameter , determ ining the amplitude of the singular term, the index 0, characterizing the nature of the singularity, and the noise parameter , determ ining the strength of the noise correlations. Speci cally, in the case of a therm all environment at temperature T the noise strength / T.

In the absence of noise this model exhibits a nite-time-singularity at a time t_0 , where the variable x vanishes with a power law behavior determined by . When noise is added the nite-time-singularity event at t_0 becomes a statistical event and is conveniently characterized by a nst-passage-time distribution W (t) [14]. For vanishing noise we have W (t) = (t t_0), restating the presence of the nite-time-singularity. In the presence of noise W (t) develops a peak about $t = t_0$, vanishes at short times, and acquires a long time tail.

The model in Eq. (1.1) has also been studied in the context of persistence distributions related to the nonequilibrium critical dynam ics of the two-dimensional XY model [15] and in the context of non-G aussian M arkov processes [16]. Finally, regularized for small x, the model enters in connection with an analysis of long-range correlated stationary processes [17].

E lectronic address: fogedby@ phys.au.dk

From our analysis in ref. [13] it followed that for = 0, the logarithm ic case, the distribution at long times is given by the power law behavior

W (t) t ; =
$$\frac{3}{2} + \frac{3}{2}$$
: (1.2)

For vanishing nonlinearity, i.e., = 0, the nite-time-singularity is absent and the Langevin equation (1.1) describes a simple random walk of the reaction coordinate, yielding the well-known exponent = 3=2 [14, 18, 19]. In the nonlinear case with a nite-time-singularity the exponent attains a non-universal correction, depending on the ratio of the nonlinear strength to the strength of the noise; for a therm all environm ent the correction is proportional to 1=T. In the generic case for > 0 we found that the fall-o is slower and that the correction to the random walk result is given by a stretched exponential

W (t)
$$t^{3=2} \exp[A(t^{=(2+)} 1)];$$
 (1.3)

where A ! = for ! 0.

In our studies so far we have ignored damping. It is, however, clear that in realistic physical situations friction or damping must enter on the same footing as the noise. This follows from the Einstein relation or more generally from the uctuation-dissipation theorem relating the damping to the noise. In the present paper we attempt to am end this situation and thus proceed to extend the analysis in ref. [13] to the case of linear damping. We shall here only consider the logarithm is case for = 0.

For this purpose we consider the following model for one degree of freedom :

$$\frac{dx}{dt} = x \frac{1}{2jxj} + ; h = (t):$$
 (1.4)

In addition to the coupling parameter , and the noise parameter , this model is also characterized by the damping constant . A sum ing for convenience a dimensionless variable x the coupling and the noise strengths and have the dimension 1=time. The ratios = and = are thus dimensionless parameters characterizing the behavior of the system.

It follows from our analysis below that the damping constant sets an inverse time scale 1 = . At intermediate time scales for t 1 the distribution exhibits the same power law behavior as in the undamped case given by Eq. (12). At long times for t 1 the distribution falls o exponentially with time constant 1 = (1 + =), i.e.,

$$W (t) / \exp[((1 + =)t]];$$
 (1.5)

The paper is organized in the following manner. In Section II we introduce the nite-time-singularity model with linear damping and discuss its properties. In Section III we review the weak noise WKB phase space approach to the Fokker-Planck equation, apply it to the nite-time-singularity problem with damping, discuss the associated dynamical phase space problem and the long time properties of the distributions. In Section IV we derive an exact solution of the Fokker-Planck equation and present an expression for the rst-passage-time distribution. In Section V we present a sum mary and a conclusion. In the present treatment we draw heavily on the analysis in ref. [13]. In Appendix A aspects of the exact solution are discussed in more detail; in Appendix B we consider the weak noise limit of the exact solution.

II. MODEL

In term s of a free energy or potential F we can express Eq. (1.4) in the form

$$\frac{\mathrm{dx}}{\mathrm{dt}} = \frac{1}{2}\frac{\mathrm{dF}}{\mathrm{dx}} + (t); \qquad (2.1)$$

where F has the form

$$\mathbf{F} = \mathbf{x}^2 + \ln \mathbf{j}\mathbf{x}\mathbf{j}; \tag{2.2}$$

The free energy has a logarithm ic sink and drives x to the absorbing state x = 0. For large x the free energy has the form of a harm onic well potential con ning the motion. In Fig. 1 we have depicted the free energy in the various cases.

A. The noiseless case

In the case of vanishing noise Eq. (2.1) is readily solved. We obtain

$$x (t) = \frac{1}{2} e^{2(t_0 - t)} \frac{i_{1=2}}{1};$$
 (2.3)

with a nite-time-singularity at

$$t_0 = \frac{1}{2} \log 1 + \frac{2}{-x_0^2} : \qquad (2.4)$$

The initial value of x is x_0 at time t = 0. In the presence of damping x initially falls o exponentially due to the con ning harmonic potential with a time constant 1=. For times beyond 1= the nonlinear term takes over and drives x to zero at time t₀, i.e., x falls into the sink in F. In Fig. 1 we have shown the noiseless solution x (t).

B. The noisy case

Sum marizing the discussion in ref. [13], the stochastic aspects of the nite-time-singularity in the presence of noise are analyzed by focusing on the time dependent probability distribution P (x;t) and the derived rst-passage-time or absorbing state probability distribution W (t). The distribution P (x;t) is de ned according to [19, 20] P (y;t) = h (y x(t)) i where x is a stochastic solution of Eq. (2.1) and h indicates an average over the noise driving x. In the absence of noise P (y;t) = (y x(t)), where x is the determ inistic solution given by Eq. (2.3) and depicted in Fig 1. At time t = 0 the variable x evolves from the initial condition x_0 , in plying the boundary condition P (x;0) = (x x_0).

At short times x is close to x_0 and the singular term and the damping term are not yet operational. In this regime we obtain ordinary random walk with the Gaussian distribution, P (x;t) = (2 t) $^{1=2} \exp$ (x $x)^2=2 t$. At a time scale given by 1= the damping drives x towards a stationary distribution given by P / exp(F=). However, at longer times beyond the scale 1=, the barrier =2x comes into play preventing x from crossing the absorbing state x = 0. This is, how ever, a random event which can occur at an arbitrary time instant, i.e., the nite-time-singularity at t_0 in the determ inistic case is electively resolved in the noisy case. For not too large noise strength the distribution is peaked about the noiseless solution and vanishes for x ! 0, corresponding to the absorbing state, implying the boundary condition

$$P(0;t) = 0:$$
 (2.5)

In order to model a possible experimental situation the rst-passage-time or absorbing state distribution W (t) is of more direct interest [20, 21].

Since P (0;t) = 0 for all t due to the absorbing state, the probability that x is not reaching x = 0 in time t is thus given by $_{0}^{}$ P (x;t)dx, in plying that the probability dW that x does reach x = 0 in time t is $dW = _{0}^{}$ dxdt(dP=dt), yielding the absorbing state distribution W (t) = $_{0}^{}$ dx @P (x;t)=@t [19]. In the absence of noise P (x;t) = (x x (t)) and W (t) = (t t), in accordance with the nite time singularity at t = t_0. For weak noise W (t) peaks about t_0 with vanishing tails for small t and large t.

The distribution P (x;t) satis es the Fokker-P lanck equation [20, 21]

$$\frac{\partial P}{\partial t} = \frac{1}{2} \frac{\partial}{\partial x} \frac{dF}{dx} P + \frac{\partial P}{\partial x} ; \qquad (2.6)$$

in the present case subject to the boundary conditions $P(x;0) = (x + x_0)$ and P(0;t) = 0. The Fokker-Planck equation has the form of a conservation law @P = @t + @J = @x = 0, dening the probability current J = (1=2) (dF = dx)P(1=2) @P = @x and we obtain for W(t) the expression

$$W(t) = \frac{1}{2} \frac{dF}{dx}P + \frac{@P}{@x}_{x=0};$$
 (2.7)

to be used in our further analysis. Note that there is a sign error in Eq. (3.8) in ref. [13].

III. W EAK NOISE APPROACH

In this section we apply a weak noise canonical phase space approach to the dam ped nite-time-singularity model and infer the general long time behavior. The treatment follows closely the analysis in ref. [13].

A. The phase space m ethod

From a structural point of view the Fokker-P lanck equation (2.6) has the form of an imaginary-time Schrödinger equation (P = (P = H P, driven) by the Ham iltonian or Liouvillian H. The noise strength plays the role of an elective P lanck constant and P corresponds to the wavefunction. D rawing on this parallel we have in recent work in the context of the K ardar-P arisi-Zhang equation for a growing interface elaborated on a weak noise nonperturbative W KB phase space approach to a generic Fokker-P lanck equation for extended system [22, 23, 24]. In the case of a single degree of freedom this method amounts to the eikonal approximation [19, 21, 25], see also [26, 27]. For system s with many degrees of freedom the method has for example been expounded in [28], based on the functional formulation of the Langevin equation [29, 30]. In the present formulation [22, 23, 24] the emphasis is on the canonical phase space analysis and the use of dynamical system theory [31, 32].

The weak noise WKB approximation corresponds to the ansatz $P / \exp[S=]$. The weight function or action S then to leading asymptotic order in satisfies a Ham ilton-Jacobi equation @S=@t+H=0 which in turn implies a principle of least action and Ham iltonian equations of motion [33, 34]. In the present context the Ham iltonian takes the form

$$H = \frac{1}{2}p(p - \frac{1}{x} - 2x); \qquad (3.1)$$

yielding the H am ilton equations of m otion

$$\frac{dx}{dt} = x \frac{dx}{2x} + p; \qquad (3.2)$$

$$\frac{d\mathbf{p}}{d\mathbf{t}} = \mathbf{p} \quad \frac{1}{2 \, \mathbf{x}^2} \mathbf{p} : \tag{3.3}$$

These equations replace the Langevin equation (1.4) with the noise represented by the momentum p = @S=@x, conjugate to x. The equations (3.2) and (3.3) determ ine orbits in a canonical phase space spanned by x and p. Since the system is conserved the orbits lie on the constant energy manifold (s) given by E = H. The action associated with an orbit from x_0 to x in time t has the form

$$S(\mathbf{x}_0 \mid \mathbf{x}; \mathbf{t}) = \int_{0}^{L_{t}} d\mathbf{t} p \frac{d\mathbf{x}}{d\mathbf{t}} \quad \mathbf{H} :$$
(3.4)

A coording to the ansatz the probability distribution is then given by

$$P(x;t) = P(x_0 ! x;t) / exp = \frac{S(x_0 ! x;t)}{(3.5)}$$

B. Long time orbits

The zero-energy manifolds delimiting the phase space orbits follow from Eq. (3.1) and are given p = 0 and p = 2 + 2 + 2x. The p = 0 sub-manifold corresponds to the noiseless or deterministic case discussed above. The p = -x + 2 + 2x sub-manifold corresponds to the noisy case. By insertion in Eq. (3.3) we obtain dx=dt = x + -2x, i.e., the motion on the noisy sub-manifold is time reversed of the motion on the noiseless sub-manifold. The orbit structure in phase space is moreover controlled by the hyperbolic xed point at $(x; p) = [(-2)^{1-2}; (2)^{1-2}]$. The heteroclinic orbits passing through the xed point are given by p = -x and p = 2 + x and the energy of the invariant manifold is E = -x. In Fig 2 we have depicted the phase space with the zero-energy manifolds, the xed point, the heteroclinic orbits and some characteristic orbits.

The long time behavior of the distribution is determined by an orbit from x_0 to x traversed in time t. In the long time limit this orbit must pass close to the hyperbolic xed point. Note that in the limit ! 0 the xed point migrates to in nity in the x direction and the long time orbits approach the zero energy sub-manifolds which thus determine the asymptotic properties as discussed in ref. [13].

Independent of whether the initial value x_0 is greater or smaller than the xed point value x, the long time orbit follows the invariant p = -x manifold towards the xed point. At the xed point the orbit slows down and then speeds up again as the orbit follows the other invariant manifold p = 2 x towards the endpoint x reached in time t. This behavior is also depicted in Fig 2.

This scenario allows a simple analysis of the long time behavior of the distribution P (x;t) and the rst-passagedistribution W (t). Close to the invariant manifolds with energy E = the action associated with an orbit from x_0 to x follows from Eq. (3.4) and is given by

$$S = E t + \frac{dx - +}{x_0} \frac{dx^2 x}{x};$$
 (3.6)

or, denoting the relevant m anifolds by a subscripts, see Fig. 2,

$$S = t + \log \frac{x}{x_0} + (x^2 - x^2)_{II}:$$
 (3.7)

At long times we only have to consider the contribution from the orbit leading up to the xed point. Inserting the manifold condition p = -x in the equation of motion (3.2) we thus obtain dx=dt = -x + -2x with solution

$$x(t)^{2} = x_{0}^{2}e^{2t} + x^{2}(1 e^{2t})$$
: (3.8)

C. Discussion

It follows from Eq. (3.8) that the damping sets an inverse time scale delimiting two kinds of characteristic behavior. First, fort! 1 the orbit approaches the xed point x. For t 1 we have $x^2 = x^2(1 \exp(2 t))$ and x approaches the xed point in an exponential fashion. On the other hand, in the interm ediate time region for t 1 and for t x_0^2 and t x_0^2 we obtain $x^2 = x_0^2 + 2t x = x_0^2 + t$ t.

By insertion in the expression (3.7) for the action we then obtain in the late time regime for t 1

S (t) t
$$\frac{1}{2}e^{2t}$$
; (3.9)

yielding the distribution and ensuing rst-passage-time distribution

$$P(t) / W(t) / exp(t=):$$
 (3.10)

Likewise, we have in the intermediate time regime t 1

$$S(t) t + \frac{1}{2} \log \frac{1}{2};$$
 (3.11)

giving rise to the distribution and st-passage-time distribution

$$P(t) / W(t) / j^{2}$$
: (3.12)

These results hold in the weak noise limit. We note that at long times W (t) falls of exponentially with a time constant given by = . In the intermediate time regime W (t) exhibits a power law behavior with exponent =2, independent of 1= dening the cross-over time. These results will also be recovered from the exact solution discussed in the next sections.

IV. EXACT SOLUTION

In this section we return to the Fokker-Planck equation (2.6) and present an exact solution. This solution is an extension of the solution presented in ref. [13] and the analysis proceeds in much the same way. Details are discussed in Appendices A and B.

A. Quantum particle in a harm onic potential with centrifugal barrier

The Fokker P lanck equation has the form

$$\frac{\partial P}{\partial t} = \frac{\partial^2 P}{\partial x^2} + x + \frac{\partial^2 P}{\partial x} + \frac{\partial^2 P}{\partial x} + \frac{\partial^2 P}{\partial x^2} P: \qquad (4.1)$$

E lim inating the rst order term by means of the gauge transform ation

$$\exp(h) = jxj^{-2} e^{x^2-2};$$
 (4.2)

we can express the equation in the form

$$\frac{\partial}{\partial t} \left[\exp(h)P \right] = H \left[\exp(h)P \right]; \tag{4.3}$$

where the Hamiltonian H driving P is given by

$$H = \frac{1}{2} \frac{2}{2} \frac{e^2}{2} + \frac{2}{8} 1 + \frac{2}{x^2} + \frac{1}{x^2} + \frac{1}{2} - 1 + \frac{2}{2} x^2:$$
(4.4)

This Ham iltonian describes the motion of a unit mass quantum particle in one dimension in a harmonic potential subject to a centrifugal barrier of strength (2 =8)(1 + 2 =) at the origin; plays the role of an elective Planck constant. Note that in Eq. (6.4) in ref. [13] the factor =2 should read 1= .

For = 0 and = 0 both the barrier and the con ning potential are absent; the spectrum of H form s a band and the particle can m ove over the whole axis. This case corresponds to ordinary random walk [19]. Incorporating the absorbing state condition in Eq. (2.5) by m eans of the m ethod of m irrors we obtain the results presented in ref. [13], i.e.,

P (x;t) = (2 t)
$$^{1=2} \exp \frac{(x x_0)^2}{2t} \exp \frac{(x + x_0)^2}{2t}$$
; (4.5)

in the half space x = 0, and for the absorbing state distribution

W (t) =
$$\frac{2}{-1} x_0 \exp(x_0^2 = 2 t)$$
 (t) $x_0^{3=2}$: (4.6)

For \notin 0 and = 0 the particle cannot cross the barrier and is con ned to either half space; this corresponds to the case of a nite-time-singularity subject to noise and an absorbing state at x = 0 and was discussed in detail in ref. [13]; for reference we give the obtained results below. Note that x and x_0 should be interchanged in Eq. (6.5) and that a factor is missing in Eq. (6.6) in ref. [13].

$$P(x;t) = \frac{x_0^{=2} + 1=2}{x^{=2} + 1=2} \frac{\exp \left(-\frac{x^2 + x_0^2}{2t}\right)}{t} I_{\frac{1}{2} + \frac{1}{2}} \frac{xx_0}{t} :$$
(4.7)

W (t) =
$$\frac{2 \times \frac{1+}{0}}{(1=2+=2)} \exp(x_0^2=2 t)(2 t)^{\frac{3}{2}}$$
: (4.8)

In the present case for \notin 0 and \notin 0 the problem corresponds to the motion of a particle in a harm onic potential with a centrifugal barrier at x = 0. The spectrum is discrete and becomes continuous for = 0. The problem is readily analyzed in terms of con uent hypergeom etric functions, more speci cally Laguerre polynom ials [35, 36]. Incorporating the initial condition P (x; 0) = (x x) and introducing the time scaled variables

$$x = x \exp(t=2);$$
 (4.9)

$$x_0 = x_0 \exp(+ t=2);$$
 (4.10)

we nd for P (x;t)

$$P(x;t) = \frac{x_0^{=2} + 1=2}{x^{=2} + 1=2} \frac{e^{t=2}}{\sinh t} \exp -\frac{(x^2 + x_0^2)}{2\sinh t} I_{\frac{1}{2} + \frac{1}{2}} - \frac{xx_0}{\sinh t} ; \qquad (4.11)$$

and correspondingly for the absorbing state distribution

$$W(t) = \frac{2 \times \frac{1+}{0}}{(1-2+-2)} \exp \frac{\times \frac{2}{0}}{2 \sinh t} \exp(t) \frac{\frac{3}{2}+\frac{1}{2}}{2 \sinh t} :$$
(4.12)

In Eqs. (4.7) and (4.11) I is the Bessel function of in aginary argument, I (z) = (i) J (iz) [37].

Focussing on the expression (4.12) for the rst-passage-time distribution W (t) we note that the damping constant de nes two distinct time regimes, 1 = setting the characteristic cross-over time. In the long time limit for t 1 the damping constant controls the behavior of W (t). From Eq. (4.12) we infer

W (t)
$$/ \frac{2 \times \frac{1+}{0}}{(1=2+=2)} - \frac{3=2+}{2} \exp[((1+=)t];$$
 (5.1)

i.e., W (t) falls o exponentially with an e ective damping constant (1 + =) renorm alized by the ratio = of the nonlinear strength to the noise strength. We note that for ! 0 the result is in accordance with the weak noise phase space derivation in Sec. III. In the interm ediate time regime for t 1 the damping constant drops out and we obtain

W (t)
$$/ \frac{2 \times 1^{+}}{(1=2+=2)} \exp(x_0^2=2 t) \frac{1}{2 t}$$
 : (5.2)

For 2 t x_0^2 the distribution W (t) exhibits a power law behavior with the same exponent 3=2 + =2 as in the undam ped case for = 0. For weak noise this result is again in agreem ent with the estimate in Sec. III.

In the short time limit W (t) vanishes exponentially and shows a maximum about the nite-time-singularity. In Fig. 3 we have depicted the rst-passage-time-distribution as a function of t. In Fig. 4 we illustrate the behavior of W (t) in a log-log representation.

In this paper we have extended the model discussed in ref. [13] to include a linear damping term. Not surprisingly, the damping changes the long time behavior of the physically relevant rst-passage-time distribution. The nite-time-singularity occurring at time t_0 in the noiseless case is still electively resolved by the noise, becoming a random event, but the power law scaling behavior with scaling exponent = 3=2 + =2 is limited to early times compared with the cross-over time 1= set by the damping constant. In the long time limit beyond 1= the damping gives rise to an exponential fall-o and the scaling property ceases to be valid. To the extent that the present simple model m ight apply to physical phenom enaw here damping is always present, we must conclude that an eventual power law scaling presum ably is connect to a time window determ ined by the size of the damping.

APPENDIX A: EXACT SOLUTION OF THE FOKKER -PLANCK EQUATION

In this appendix we discuss the exact solution of the Fokker-P lanck equation in m ore detail. D enoting the norm alized eigenfunction of H in Eq. (4.4) and the associated eigenvalues by $_{n}$ and $^{2}E_{n}=2$, respectively, we obtain, incorporating the initial condition P (x;0) = (x x) and the gauge transform ation, the following expression for the distribution

$$P(x;t) = \int_{n}^{X} e^{\sum_{n} t = 2} e^{(x^{2} - x_{0}^{2}) = 2} (x = x_{0})^{-2} \int_{n}^{n} (x) \int_{n}^{n} (x_{0}):$$
(A1)

By means of the transformation $(x) = x^{1+} = \exp x^2 = 2$ G ($x^2 =$) it follows that G is a solution of the degenerate hypergeometric equation [35, 36]. For the discrete spectrum we choose the polynomial form and further analysis shows that the eigenfunctions n are given in terms of the Laguerre polynomials L_n [35, 36]. For the normalized eigenfunctions we thus obtain

$$n = 2 - \frac{3=2+=2}{(3=2+=2+n)} \frac{(n+1)}{(3=2+=2+n)} x^{1+=2} e^{x^2=2} L_n^{1=2+=2} (x^2=);$$
 (A2)

with discrete eigenvalue spectrum

$$E_n = 4n = +2(=)(1+=)$$
: (A3)

Inserting Eqs. (A 2) and (A 3) in Eq. (A 1) and using the identity [35, 36]

$$\frac{X}{(n+1)} \frac{n!}{(n+1)} z^{n} L_{n}(x) L_{n}(y) = \frac{(xyz)^{-2}}{1 z} e^{-z (x+y)(1-z)} I (2 (xyz)^{1-2} = (1-z));$$
 (A4)

we nally obtain Eq. (4.11) for P (x;t) and by the same analysis as in Ref. [13] the expression (4.12) for W (t). We note that for ! 0, using $I_{1=2}(x) = (2=x)^{1=2} \sinh x$ [35], the expression (4.11) takes the form

$$P(x;t) = \frac{(1 e^{2t})}{(1 e^{2t})} \exp -\frac{(x x_0 e^{-t})^2}{1 e^{2t}} \exp -\frac{(x + x_0 e^{-t})^2}{1 e^{2t}} :$$
(A5)

i.e., the mirror case of the noise driven overdam ped oscillator. Note 1) that for ! 0 the variable x lies on the noiseless orbit x $! x_0 \exp((t) \operatorname{and} 2) P$ vanishes for x = 0.

APPENDIX B:SMALL NOISE LIM IT -SADDLE POINT ANALYSIS

In this appendix we perform for completion a weak noise saddle point analysis of the exact expression in Eq.(4.11) along the same lines as in ref. [13]. This analysis requires that we consider both large order and argument of the Bessel function I (x). This is easily done by Laplace's method using a convenient spectral representation [35, 36]

$$I(z) = \frac{(z=2)}{(+1=2)(1=2)} \int_{0}^{Z} \cosh(x \cos x) \sin^{2} dz;$$
(B1)

Inserting (B1) in (4.11) we have

$$P(\mathbf{x};t) = \frac{1}{4} \frac{1}{2} \frac{1}{\mathbf{x}_0} - e^{=2} \frac{\mathbf{x}_0^2}{\sinh t} e^{(-4)(\mathbf{x}^2 + \mathbf{x}_0^2) = (\mathbf{x}\mathbf{x}_0 \sinh u)} e^{t=2}$$

$$d \frac{\sin u}{\sinh u} e^{(-1)(\log \sin u + (1-2)\cos u - \sinh u)} + e^{(-1)(\log \sin u - (1-2)\cos u - \sinh u)}; \quad (B2)$$

where u is defined by $\sinh u = \sinh t = (2 \times x_0), x = x \exp(t=2), \text{ and } x_0 = x_0 \exp(t=2).$ Setting f() = log sin (1=2) cos = sinh u the saddle points for small are given by cos = exp(u) for x > 0 and cos = exp(u) for x < 0. For x > 0 we have f_+(+) = f() = (1=2)(log(1 e^{2u}) + e^{u} = sinh u) and f_+^{(0)}(+) = f^{(0)}() = coth u, and we obtain the weak noise result for x > 0

$$P(x;t) = \frac{1}{4} \frac{e^{t=2}}{x_0} \frac{x_0^2 (1 e^{2u})}{\sinh t} \xrightarrow{1=2+2} \frac{e^{(-2u)(x^2 + x_0^2 2xx_0 \cosh u) = xx_0 \sinh u}}{(\sinh u \cosh u)^{1=2}};$$
(B3)

For ! 0 the factor $x^2 + x_0^2 = 2xx_0 \cosh u$ in the exponent in (B 3) locks onto zero, thus setting $x^2 + x_0^2 = 2xx_0 \cosh u = 0$ and inserting sinh $u = \sinh (t) = 2 xx_0$ we obtain

$$x^{2} + x_{0}^{2}$$
 $((2xx_{0})^{2} + (\sinh t =)^{2})^{1=2} = 0$: (B4)

Finally, setting $x = x \exp(t=2)$ and $x_0 = x_0 \exp(t=2)$ we obtain after some reduction

$$x (t) = \frac{q}{x_0^2 \exp(2 t)} (=2)(1 \exp(2 t));$$
(B5)

which by simple inspection is equivalent to to Eq. (2.3. For ! 0 we have $x = \frac{p_{12}}{x_0^2}$ t; for ! 0, $x = x_0 e^{-t}$.

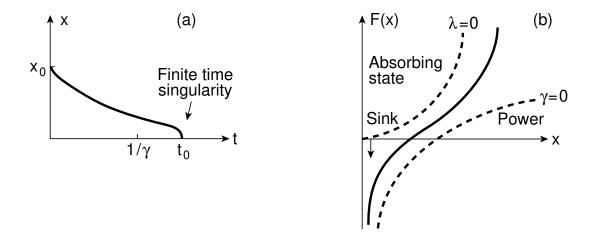

FIG.1: In a) we show the time evolution of the single degree of freedom x. At times shorter than the cross-over time l = the variable x falls o exponentially. At times beyond l = the variable x reaches the absorbing state x = 0 at a nite time t_0 . In b) we depict the free energy F (x) driving the equation. For = 0 the free energy forms a conning harmonic well, for = 0 we have the absorbing state case discussed in ref. [13]. In the general case the absorbing state x = 0 corresponds to the sink in F (x).

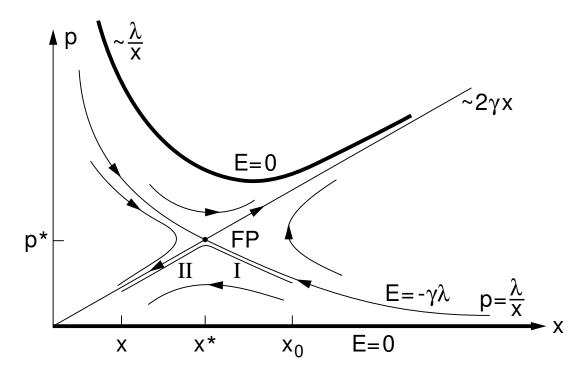

FIG.2: We show the topology of phase space. The bold lines indicate the zero energy sub-m anifolds. The invariant heteroclinic orbits $p = 2 \times and p = -x$ passing through the saddle point FP at $(x; p) = [(-2) 1=2; (2)^{1-2}]$ have energy . The arrows indicate the direction of the ow. The long time orbit from x_0 to x passes close to the xed point. The part of the orbit following the invariant manifold p = -x and entering in our long time estimate is denoted I; the part of the orbit close to the $p = 2 \times m$ anifold is denoted II.

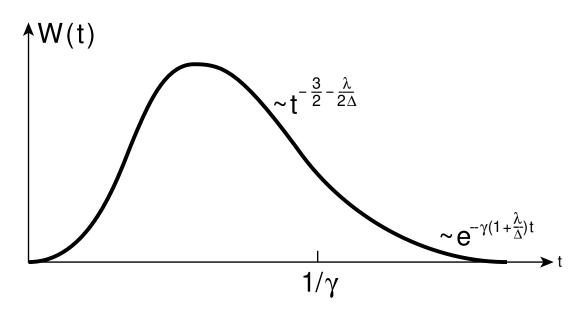

FIG.3: We sketch the rst-passage-time distribution W (t) as a function of t. In the limit ! to W (t) vanishes exponentially; about the nite-time-singularity W (t) exhibits a maximum. At intermediate times for t 1 the distribution exhibits a power law behavior with scaling exponent 3=2 + =2. In the long time limit for t 1 an exponential fall-o with time constant (1 + =) characterizes the behavior of W (t)

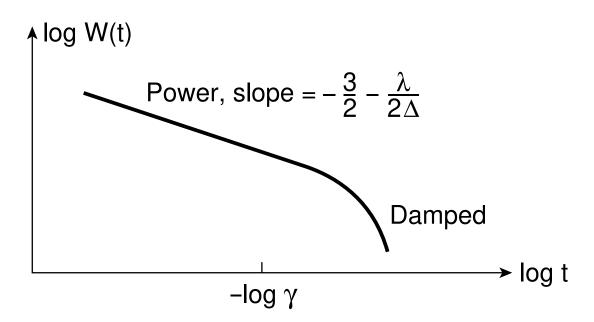

FIG.4: In this gure we sketch the behavior of W (t) in a log-log plot. At intermediate times earlier that 1 = we have scaling behavior with exponent 3=2 + =2, corresponding to a constant negative slope. In the long time limit the curve dips down indicating the cross-over to exponential behavior.
