Depending on the Hamiltonian parameters, two-component bosons in an optical lattice can form at least three different superfluid phases in which both components participate in the superflow: a (strongly interacting) mixture of two miscible superfluids (2SF), a paired superfluid vacuum (PSF), and (at a commensurate total filling factor) the super-counterfluid state (SCF). We study universal properties of the 2SF-PSF and 2SF-SCF quantum phase transitions and show that (i) they can be mapped onto each other, and (ii) their universality class is identical to the $(d+1)$ -dimensional normal-superfluid transition in a single-component liquid. Finite-temperature 2SF-PSF (SCF) transitions and the topological properties of 2SF-PSF (SCF) interfaces are also discussed.

Recent remarkable success in experimental study of ultra-cold atoms in a 3D optical lattice (OL) [1] signals a major breakthrough in the field of strongly-correlated quantum lattice systems. A simple theoretical framework which adequately describes physics of atomic gases in OL is given by the on-site Bose-Hubbard model [2]. Its seminal prediction [3] the superfluid (SF) (Mott-insulator (MI) transition) has been unambiguously confirmed [1].

Realistic experimental perspectives of trapping several atomic species in ultra-quantum regime have inspired theoretical studies of multi-component systems in OL [4, 5, 6]. In particular, it has been argued that the two-component commensurate mixture of inconvertible atoms can be in the super-counterfluid state (SCF) [5]. In this state, the net atomic superfluid current is impossible, and yet the equal-current flows of two components in opposite directions are superfluid. Another intriguing superfluid groundstate which exists in the two-component (with equal particle numbers) Bose system in OL is the paired superfluid vacuum (PSF) [7, 8]. Qualitatively, this state is equivalent to the superfluid state of two-atomic molecules and a BCS superconductor. An important quantitative difference with the BCS theory is that bosonic superfluidity exists without pairing correlations too, and PSF is always associated with finite intra-species interaction. At the moment, it is not clear whether PSF can be realized in atomic gases without OL. At the 2SF-PSF transition point the pairing interaction is necessarily strong, i.e. the scattering length for atoms ready to form a pair is of the order of (or larger) than the interatomic separation. Under these conditions, metastable atomic gases are likely to become unstable from the experimental point of view because of very large inelastic cross-sections leading to formation of fast tight molecules (not to be confused with loose pairs we are discussing here) and fast atoms. In OL, this recombination channel is not an issue since now the regime of strong/weak interaction is controlled by the ratio of the tunnelling constant to the

strength of the effective on-site interaction, while decay rates are still controlled by the one-site physics and are not sensitive to tunnelling.

In this Letter, we discuss universal properties of the 2SF-PSF and 2SF-SCF phase transitions. First, we prove that the two transitions are equivalent to each other by establishing mapping between the PSF and SCF phases. According to mapping, SCF can be viewed as a "molecular" superfluid, where "molecules" consist of particles of one component and holes of another component. Correspondingly, the SCF transition is equivalent to binding of two atomic superfluids into PSF. Our main focus is on the quantum phase transition. We present strong arguments that this transition is in the $(d+1)$ -dimensional U(1) universality class, and propose an effective $(d+1)$ -dimensional classical model describing it. It allows us to relate correlation functions in terms of the original bosonic fields to correlators of the U(1) order parameter. In the vicinity of the quantum phase transition point, our considerations are naturally generalized to the finite-temperature case, predicting the same U(1) universality class (but now in d dimensions) for the 2SF-PSF (SCF) transition at $T > 0$. We verify our predictions numerically by performing Monte Carlo simulations of a 3D two-component closed-loop current model of Ref. [9] which long-range critical behavior is identical to that of a two-component 2D quantum system. Finally, we note that the 2SF-PSF (SCF) phase transition preserves the "molecular" part of the order parameter and discuss consequences of this fact for the structure of vortices in hybrid systems containing 2SF-PSF (SCF) interfaces.

The qualitative equivalence of PSF and SCF phases can be understood on the basis of Feynman's representation of quantum statistics in terms of particle paths (worldlines) in imaginary time β [10; 11], where β is the inverse temperature. In this representation, the superfluid groundstate is characterized by worldlines forming macroscopic cycles (for brevity, we call them M -

cycles), when the end of one worldline at $t = t_1$ is the beginning of another worldline at time $t_2 = 0$, and so on (partition function worldlines in imaginary time are β -periodic). The qualitative difference between the 2SF and P SF groundstates is that in P SF each A-component worldline is bound to some B-component worldline, and in the long-range limit there are no free single-component worldlines forming independent M-cycles. All M-cycles are formed only by pairs of lines, and we arrive at the picture of P SF, or molecular superfluid. Less obvious is the fact that SCF has the same worldline structure as P SF. The key observation is that for integer total filling factor one may use a hole representation for one of the components, say, component B. We readily understand that the only worldline structure consistent with the absence of net superfluid response is when each B-hole worldline is bound with some A-particle worldline| this is the only possibility of forming M-cycles out of particle-hole pairs without having independent single-component M-cycles. Macroscopically, bound particle-hole pairs behave like new "molecules" with zero particle number charge, and their flow is equivalent to the counter-flow of participating components.

In view of the SCF-P SF equivalence, in what follows we discuss P SF only, implying that all results remain valid for SCF as well.

The worldline language presents also a "graphic picture" of critical fluctuations driving the P SF-2SF transition. Suppose that initially we are deeply in the P SF phase. Then each A-line is closely followed by some B-line. As the coupling between components becomes weaker, bound lines demonstrate local unbinding fluctuations, see Fig. 1 (a). These fluctuations can be viewed as single-colored oriented loops, one part of the loop representing, say, an A-line, and the other part representing a B-line with the reversed direction, see Fig. 1 (b). Close to the critical point, unbinding loops grow larger and start reconnecting with each other (become dense). We assume that only large-scale loops are essential for characterizing the universality class of the transition; the details of short-range behavior are simply determining parameters of the critical action for these loops. The phase transition in a system of oriented loops in $(d+1)$ dimensions (leading to the appearance of macroscopic-size loops) is known to describe the SF-MI transition in a commensurate system of bosons on a d -dimensional lattice (see, e.g. [9]). In its turn, this transition is equivalent to the finite-temperature phase transition between normal and superfluid states in $(d+1)$ dimensions [3]. Hence, the above reasoning suggests a mapping between the P SF-2SF and M I-SF transitions, and establishes that the P SF-2SF transition is in the universality class of classical $(d+1)$ -dimensional $U(1)$ models.

We now argue that in the long-wave limit our system can be also mapped onto a $(d+1)$ -dimensional model of two-color classical rotators. This mapping is used to have one more argument in favor of the $U(1)$ universality class, and to establish important relations between basic

FIG. 1: (a) Unbinding fluctuations of two coupled worldlines of the two-component system. (b) The single-loop effective representation. Worldlines of different species are depicted as solid and dotted lines, respectively

correlation functions; it also provides a natural generalization of our considerations to finite temperatures.

The presence of lattice commensurability is not crucial for the P SF-2SF transition since both phases involved are superfluid. However, it proves convenient to formally assume that we are dealing with the double-commensurate system| filling factors of both species are integer. According to [3], commensurate d -dimensional lattice bosons map in the long-wave limit to a $(d+1)$ -dimensional array of rotators with the Hamiltonian

$$H = \sum_{\langle ij \rangle} \cos(\phi_i - \phi_j); \quad (1)$$

where $\phi_j \in [0; 2\pi)$ is the angle of the j -th rotator (or phase of the bosonic order-parameter field $\psi(j) = e^{i\phi_j}$) and $\langle \cdot \rangle$ stands for the nearest neighbor sites on a square lattice. In our case, we need three quantum fields: ϕ_A and ϕ_B for the two components, and the field ϕ_P for the pairs. This suggests terms similar to Eq. (1) for each of the corresponding three phases. However, one also has to account for the terms in the effective Hamiltonian converting a bound pair into two atoms and vice versa. In terms of the rotator model, this leads to a local term $\sum_j \cos(\phi_j^{(P)} - \phi_j^{(A)} - \phi_j^{(B)})$ reducing the symmetry of the three-color rotor system down to $U(1) \times U(1)$. This term introduces some (loose) constraint on the difference between the phase $\phi_j^{(P)}$ and the sum, $\phi_j^{(A)} + \phi_j^{(B)}$. Replacing it with the rigid constraint $\phi_j^{(P)} = \phi_j^{(A)} + \phi_j^{(B)}$, we reduce the number of independent variables from three to two| as one could expect from the very beginning given the original $U(1) \times U(1)$ symmetry of our system. As a result, we arrive at the following Hamiltonian (for simplicity, we assume exchanging symmetry between the components):

$$H = \sum_{\langle ij \rangle} (J_1 \cos \phi_{ij} + J_2 \cos \phi_{ij}^{(A)} + J_2 \cos \phi_{ij}^{(B)}); \quad (2)$$

$$j = \frac{(A)}{j} + \frac{(B)}{j}; \quad (3)$$

where $i_j = i_j$ and $\frac{(A;B)}{ij} = \frac{(A;B)}{i} \frac{(A;B)}{j}$. Apart from the 2SF-PSF transition, this model can be also used to describe other phase transitions in the doubly commensurate system, but not otherwise.

It is convenient to introduce the phase difference

$$j' = \frac{(A)}{j} - \frac{(B)}{j} = 2; \quad (4)$$

and to rewrite the Hamiltonian (2) as ($j' = j' - j'$)

$$H = \sum_{\langle ij \rangle} [1 \cos i_j + 2 \cos(i_j - 2) \cos j'] : \quad (5)$$

[The elds and j' describe charge and pseudo-spin degrees of freedom, respectively.] Though the new variables, j and j' , cannot be interpreted as angles of new rotators, the configurational space of the original rotators $\frac{(A)}{j}$ and $\frac{(B)}{j}$ is exhausted with, say, $j \in [0; 2\pi)$ and $j' \in [-\pi; \pi]$, while the Hamiltonian (5) is not 2-periodic with respect to j for our purposes it is sufficient that just j' can be viewed as a rotator angle. Indeed, in both PSF and 2SF, the pair phase variable j is ordered and its local fluctuations are not relevant to the criticality of the 2SF-PSF transition. Therefore, we may simply set $j = 0$ in Eq. (5) which brings us to the effective one-component rotor model for j' :

$$H_{2SF-PSF} = \sum_{\langle ij \rangle} \cos j' : \quad (6)$$

The transition thus is the superfluid-normal fluid transition in the j' -channel (which means localization in the pseudo-spin sector); the corresponding complex order parameter is $\langle X \rangle / e^{i\langle X \rangle}$, where X is the space-time radius-vector treated as a continuous variable in the long-wave limit. Given this order parameter and Eq. (4) relating j' to the original phases ($\frac{(A)}{j} = \frac{(B)}{j} = j'$), we immediately find the critical behavior of various correlation functions

$$\begin{aligned} h_A^Y(X) &= h_A(0) i h_B^Y(X) = h_B(0) i h_A(X) = h_A(0) h_B(X) i \\ h^Y(X) &= h(0) i : \quad (7) \end{aligned}$$

Now we note that $(d+1)$ -dimensional model (6) with large but finite size in the j' -direction describes the initial part of the finite-temperature 2SF-PSF line in the vicinity of the quantum critical point. We thus establish the universality class $U(1)$ in d dimensions for the finite-temperature second-order 2SF-PSF transition. Since the order parameter for the transition is $e^{i\langle X \rangle}$ ("molecular" order parameter is not critical), we arrive to a rather counter-intuitive conclusion that with increasing temperature the transition is from 2SF to PSF. [Clearly, relations (7) take place on the finite-temperature critical line as well.]

This finite-temperature 2SF-PSF transition survives even when the two components have slightly different

FIG. 2: Different geometries of PSF-2SF interfaces. (See discussion in the text.)

densities and the groundstate is inevitably 2SF (both h_A and h_B are non-zero). Away from the quantum critical point, the 2SF-PSF transition can be viewed as the superfluid to normal fluid transition in the (dilute) sub-system of excessive particles.

Equation (5) is also useful for understanding the structure of vortices across the interface between the PSF and 2SF phases. Experimentally, interfaces naturally arise in inhomogeneous systems (in a confining potential, particle densities drops to zero at the boundary, and, e.g. the SCF phase, which requires commensurability, may not survive at the edge). Suppose one creates a vortex in a PSF phase and then adiabatically removes OL and the trapping potential to observe the system by the standard technique of absorption imaging [15]. When the lattice potential is turned off, the system will behave as two weakly interacting gases. The question now is: Do vortices in the PSF phase transform (and how) into vortices in the resulting weakly interacting system [10]?

System inhomogeneity implies that at intermediate stages of the potential turning off, there will be an interface similar to one shown in Fig. 2(a). Ultimately, the interface shrinks and disappears with the PSF phase, while the topological structure of the 2SF state remains the same as it was when the interface existed. To understand this structure we resort to the rotator model (5). In both PSF and 2SF the phase eld is ordered and thus the circulation of r does not change across the interface. Since the phase eld j' is disordered inside the PSF phase, there are no topological constraints associated with it. Taking into account (3), we arrive at the following rule for topological charges:

$$I^{(A)} + I^{(B)} = I; \quad (8)$$

where $I^{(A;B)}$ and I are integer topological charges in 2SF and PSF correspondingly

$$I^{(A;B)} = \frac{1}{2} \int_{C_2} r^{(A;B)} dl; \quad I = \frac{1}{2} \int_{C_1} r dl : \quad (9)$$

We see that vortices in PSF always induce vortices in the 2SF phase elds $\frac{(A)}{j}$ or/and $\frac{(B)}{j}$, and thus makes it possible to observe the circumstantial evidence of the PSF

vortex in the absorption in age of the weakly interacting 2SF state. However, the values of topological charges are not unambiguously defined. For example, if $I = 1$ then $(I^{(A)} = 1; I^{(B)} = 0)$ and $(I^{(A)} = 0; I^{(B)} = 1)$, are consistent with Eq. (8), as well as, say, $(I^{(A)} = 2; I^{(B)} = -1)$. This implies that particular values of $I^{(A)}$ and $I^{(B)}$ will depend on details of the experimental setup determining the lowest energy configuration. For example, if the two components have different superfluid stiffnesses and, initially, there was one vortex in the PSF, then, after creating the interface and removing the PSF, the vortex will reside in the component with lower stiffness.

Another interesting geometry is shown in Fig. 2(b). Using arguments identical to those presented above, we see that the only integer topological charge on contour C is I . While the sum of integrals for $I^{(A)}$ and $I^{(B)}$ still equals I , separately they are illdefined on C , because the phase θ experiences large zero-point fluctuations in the PSF region. Suppose, then, that initially there were no PSF phase at all, and the topological charges of components were, say, $I^{(A)} = 1$ and $I^{(B)} = 0$. Imposing OL to create PSF will eliminate quantization for the individual phases $\theta^{(A,B)}$, while preserving the sum $I^{(A)} + I^{(B)} = 1$. Accordingly, since no memory about the initial values $I^{(B)}$; $I^{(A)}$ is retained, further removal of the OL may result in the final 2SF state with $I^{(A)} = 0; I^{(B)} = 1$. Similarly to the previous setup, if the two components have different superfluid stiffnesses, then, after the cycle of switching on and off OL, the circulation will reside in the component with lower stiffness.

There are several options to verify above considerations numerically. One is a direct simulation of the two-component d -dimensional Bose-Hubbard Hamiltonian at very low temperature. However, the universality class of the phase transition and the relevant long-wave description of critical fluctuations, may be also obtained for the $(d+1)$ -dimensional classical lattice model built on particle trajectories in discrete imaginary time. One of the quantum-to-classical mappings for the Bose-Hubbard Hamiltonian, the J-current model, was developed in

Ref. [9], and we straightforwardly generalized it to the two-component case. Our choice to simulate the classical action was motivated only by reasons of numeric efficiency. Recently developed quantum and classical Worm Algorithms do not suffer from critical slowing down [11], but the classical one is superior because of its simplicity (it was already successfully applied to the disordered one-component J-current model [12]). We defer details of simulations performed for the $d+1 = 3$ case to a longer paper [13] and simply mention here results. The correlation radius and the correlation function exponents for the 2SF-PSF transition agreed with the known values for the 3D U(1)-universality class [14] within 1–2% accuracy. We have directly verified that non-trivial relations between the correlation functions given by Eq. (7) hold true at the critical point, and deviations from Eq. (7) are barely visible even at distances as small as 5 lattice constants. We have observed the qualitative prediction of the model (6) about the transition from 2SF to PSF with increasing temperature.

Summarizing, we have shown that two strongly-correlated phases of the two-component bosonic system, the superfluid state of pairs and the counterflow superfluid, are macroscopically equivalent. We have presented arguments supported by results of numeric simulations, that quantum phase transitions leading to formation of these phases from the state of two miscible superfluids are in the universality class of superfluid-Mott-insulator transition in a single-component bosonic system. The finite-temperature 2SF-PSF (SCF) transitions are in the universality class of a single-component superfluid-normal fluid transition. The proposed two-color rotator model correctly describes the critical behavior of various correlators and, in the spatially inhomogeneous case, yields a simple rule for "sewing" topological defects across the boundary between the phases. On the basis of this rule it is possible to observe the evidence of the 2SF-PSF (SCF) phase transitions even without directly detecting it.
