

Intrinsic tunneling or Joule heating?

In a recent letter [1] Yurgens et al. reported superconducting s and normal p (pseudo)gaps in the c -axis differential conductance of Bi2201-La mesas and ruled out a precursor Cooper pair scenario as an explanation of p , while mechanism based on the Van Hove singularity in the density of states, or on the resonant tunnelling between CuO_2 planes, were outlined as possible explanations of the normal state pseudo-gap. I will show that a Joule heating of mesas may cause $I(V)$ nonlinearities similar to those observed in Ref.[1].

This approach provides a natural explanation of another finding of Yurgens et al. [1], the surprising similarity between the 'intrinsic Josephson effect' (IJE) characteristics of Bi2201 and Bi2212 despite of a threefold difference in their critical temperatures. Moreover, similar (to those applied to Bi2212) levels of dissipation (estimated as $VI=A$) are required to achieve the characteristic features of IJE-spectra of Bi2201 at the same temperature, 4.2-4.5K (Fig.1,2a [1]) namely, 0.03-0.1, 0.6-3.9, and 2.5-15.6 $\text{kW}=\text{cm}^2$ for the end of brush', s and p respectively (the scatter reflects an uncertainty in the mesa area, A , in [1]). The relevance of heating in Bi2212 is experimentally confirmed by different methods; in particular, significant overheating of the mesa's surface was reported by [2,3] even in the 'brush'-like part of $I(V)$. I believe that the character of Joule heating of a sample with typical c -axis $R(T)$ dependence, may be responsible for the similarities reported in [1].

Here I will show that the 'tunnelling characteristics' from Fig.4 [1] could be reproduced qualitatively and quantitatively using the experimental out-of-plane normal state resistance $R_c(T)$ (inset in Fig.4 of Ref.[1]) and assuming that the heating of the mesa caused by the Joule dissipation is the only reason for effects observed at high bias. Using Newton's Law of Cooling (1701), the temperature of a thin mesa is given by

$$T = T_0 + IV = (Ah); \quad (1)$$

where T_0 is the temperature of a coolant medium (liquid or gas) and h is the heat transfer coefficient. According to Eq.(1), monitoring $I(V)$ at certain base temperature T_0 results in a sample temperature rise that entails non-linearity in $I = V/R_c(T)$. Thus constructed dI/dV curves resemble those presented in Fig.4 [1]. This similarity allows for an estimate of the inverse heat transfer coefficient $(hA)^{-1} \sim 62.5\text{K}=\text{mW}$ and overheating at high bias, $\sim 80\text{K}$ for $T_0 = 200\text{K}$; the set of curves accounting for this coefficient is shown in Fig.1. As it is clearly seen from Fig.1, the 'heating' spectra taken at $T_0 < T$ reveal a 'pseudo-gap' which disappears entirely as soon

as $T_0 > T$. This result shows that Eq.(1) provides a natural explanation of some of the puzzling findings of [1].

To conclude, the nonlinear $I(V)$ characteristics observed by [1] in Bi2201 mesas are related to the temperature dependence of the normal state c -axis resistance, rather than to the 'Josephson tunnelling' between the

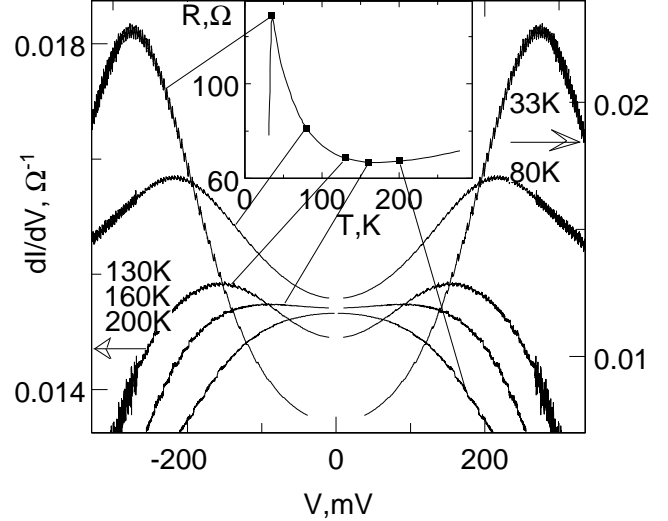

FIG. 1: dI/dV obtained from $R_c(T)$ of [1] (shown in the insert) assuming Joule heating origin of $I(V)$ nonlinearities.

planes. As far as the unusual $R_c(T)$, itself is concerned, a few models were proposed. In particular, the $R_c(T)$ explanation in the framework of the bipolaron model of cuprates [4] was supported experimentally [5]. In this model the temperature-independent-pseudogap is half of the binding energy of bipolarons. Although only the normal state data were considered here, there is no doubt that heating plays an even more important role at low temperatures, so that heating issues have to be accounted for in the analysis of the low temperature data also.
