#### Abstract

W e show that the icosahedral packings of protein capsom eres proposed by C aspar and $K$ lug for spherical viruses becom e unstable to faceting for su ciently large virus size, in analogy w ith the buckling instability of disclinations in two-dim ensional crystals. O urm odel, based on the nonlinear physics of thin elastic shells, produces excellent one param eter ts in real space to the full threedim ensional shape of large spherical viruses. The faceted shape depends only on the dim ension less Foppl-von K arm an number $=\mathrm{YR}^{2}=$, where $Y$ is the two-dim ensional Young's modulus of the protein shell, is its bending rigidity and $R$ is the $m$ ean virus radius. T he shape can be param $e-$ terized $m$ ore quantitatively in term $s$ of a spherical harm on ic expansion. W e also investigate elastic shell theory for extrem ely large, $10^{3} \ll 10^{8}$, and nd results applicable to icosahedral shapes of large vesicles studied $w$ th freeze fracture and electron $m$ icroscopy.

## I. INTRODUCTION

U nderstanding virus structures is a rich and challenging problem [1], w ith a wealth of new inform ation now becom ing available. A though traditional X -ray crystallography still allow s the $m$ ost detailed analysis [2] ], threedim ensional reconstructions of icosahedral viruses from cryo-electron $m$ icrographs are now becom ing routine [B]. $E$ lectron $m$ icroscope im ages of $m$ any identical viruses in a variety of orientations are used to reconstruct a threedim ensional im age on a com puter, sim ilar to CT (computed tom ography) scans in $m$ edical im aging. There are now, in addition, beautiful single $m$ olecule experim ents $w h i c h ~ m$ easure the work needed to load a vinus (bacteriophage 29) w ith its DNA package [4]. The aim of this paper is to explore the elastic param eters and physical ideas which determ ine the shapes of viruses $w$ th an icosahedral sym $m$ etry, using the theory of thin elastic shells [b].

The analysis of approxim ately spherical viruses dates back to pioneering w ork by C rick and W atson in 1956 [6], who argued that the sm all size of the viral genom e requires identical structural units packed together $w$ ith an icosahedral sym $m$ etry. These principles were put on a m basis by C aspar and K lug in 1962 7], who showed how the proteins in a viral shell (the \capsid") could be view ed as icosadeltahedraltriangulations of the sphere by a set of pentavalent and hexavalent $m$ orphological units ( capsom ers"). The viral shells (there can also be an outer envelope com posed ofadditionalproteins and $m$ em brane elem ents from the host cell) are characterized by a pair of integers ( $h ; k$ ) such that the number of $m$ orphological units is $N=10\left(h^{2}+h k+k^{2}\right)+2$. To get from one pentavalent capsom er to another, one $m$ oves $h$ capsom ers along a row of near-neighbor bonds on the

FIG.1: A right-handed $(3,1)$ triangulated net (icosadeltahedron) used to describe virus structure. T he $(1,3)$ structure is left-handed.
sphere, tums 120 degrees and m oves another $k$ steps. Euler's theorem relating the number of vertices, edges and faces of a spherical triangulation insures that the num ber of capsom ers in ve-fold environm ents is exactly 12 [8]. A simple icosahedron of 12 m onphological units corresponds to $(1,0)$ while soccer balls and $C_{60}$ fullerene molecules are $(1,1)$ structures $w$ ith $\mathrm{N}=32$ polygons. A $(3,1)$ icosadeltahedron $N=132$ is shown in $F$ ig. 1 . The polyom a virus (SV 40) is a $(2,1)$ structure with 72 capsom eres, while the much larger adenovinus and herpes sim plex virus are $(5,0)$ and $(4,0)$ structures w ith 252 and 162 m onphologicalunits, respectively. Structures like that in $F$ ig. 1 w ith h and k nonzero and $\mathrm{h} \in \mathrm{k}$ are chiral.
$N$ ote that the relatively sm allpolyom a virus (diam eter

FIG. 2: The polyom a virus (a) is approxim ately spherical, while the larger adenovirus (b) is m ore faceted (not to scale). Im ages from $R$ ef. [g].

440 A ngstrom s) is round (see Fig. 2 a ), while the m uch larger herpes sim plex virus (diam eter 1450 A ngstrom s) has a m ore angular or faceted shape [g] (see Fig. [2b). Faceting of large viruses is in fact a com $m$ on phenom enon; the protein subunits ofdi erent viruses, $m$ oreover, are very sim ilar (see below ). If these protein assem blies are characterized by elastic constants and a bending rigidity [5], we can ask how deviations from a spherical shape develop w ith increasing virus radius, which scales roughly as the square root of the num ber ofm onphologicalunits.

In support of the idea that virusesw ith di erent overall capsid size are com posed of nearly identical m onom ers, we note that m ost viral coat and capsid proteins have about the sam e size, $m$ olecular weight, am ino acid com position and, m ost im portantly, the sam e folded structure in three dim ensions [10]. It is known, m oreover, that protein structure determ ines the $m$ echanicalproperties of proteins [11, 12]. H ence, the sim ilarity of the protein structure of the coat/capsid proteins suggests sim ilar $m$ echanical properties. In addition, the presence of the sam e fold of capsid proteins in unrelated viruses (bacterial phages, plant viruses, insect viruses and anim al viruses) indicate that the fold and its $m$ echanical properties are conserved in evolution and could be essential for proper virus assem bly.

In this paper, we argue that the faceting of large viruses is caused by a buckling transition associated with the 12 isolated points of 5 -fold sym $m$ etry. These singularities can be view ed as disclinations in an otherw ise 6 -coordinated $m$ edium. It is well known that the large strains associated with an isolated disclination in a at disk spanned by a triangular lattice leads to buckling into a conical shape for [13, 14]

$$
\begin{equation*}
Y R^{2}=\quad 154 ; \tag{1}
\end{equation*}
$$

where $Y$ is the two-dim ensionaly oung'sm odulus, is the

FIG. 3: The vefold disclination in a triangular lattice. In viruses, the points would correspond to capsom eres, while in lecith in vesicles they correspond to lipid molecules. T he highly strained at space con guration is shown in (a). The buckled form which arises for 154 is shown in (b).
bending rigidity and $R$ is the disk radius. $T$ he energy of a single 5-fold disclination $w$ ith \charge" $s=2=6$ centered in a at array of proteins of size $R$ is approxim ately

$$
\begin{equation*}
\mathrm{E}_{5} \quad \frac{1}{32} \mathrm{~s}^{2} \mathrm{YR}^{2}: \tag{2}
\end{equation*}
$$

H owever, above a critical buckling radius $R_{b}$ $\overline{154=Y}$, is there a conical deform ation (see Fig. 3) such that the disclination energy now only grows logarithm ically w ith R

$$
\begin{equation*}
E_{5} \quad(=3) \quad \ln \left(R=R_{b}\right)+\frac{1}{32} s^{2} Y R_{b}^{2}: \tag{3}
\end{equation*}
$$

O ne m ight expect a sim ilar phenom enon for 12 disclinations con ned to a surface with a spherical topology. Indeed, the elastic energy for 12 disclinations on an undeform ed sphere ofradiusR is has a form sim ilarto Eq. (2), nam ely [15]

$$
\begin{equation*}
\text { E } \quad 0: 604\left(5^{2} Y^{2}=4\right) ; \tag{4}
\end{equation*}
$$

where the sphere radius $R$ now plays the role of the system size. A though it seem s highly likely that these 12 disclinations can lower their energy by buckling for large $R$, the nonlinear nature of the underlying elastic theory [5] leads to com plex interactions betw een the resulting conical deform ations. A boundary layer analysis of the von Karm an equations for bent plates predicts anom alous scaling for the $m$ ean curvature in the vicinity of the ridges connecting conical singularities [16, 17]. Interesting scaling behavior also arises in the vicinity of the apexes of the cones them selves [18]. A nother interesting physical realization of the buckling problem lies in the faceting of lecithin vesicles at tem peratures suf-
ciently low so that the lipid constituents have crystallized [19,20].

In this paper, we study the ground states of crystalline particle arraysw ith 12 disclinations in a sphericalgeom etry. $W e$ nd that there are indeed striking $m$ anifestations of the buckling transition even in the curved geom etry of
viral capsids or crystalline vesicles. The nonlinear Fopplvon K arm an equations for thin shells w ith elasticity and a bending energy are solved using a oating $m$ esh discretization developed and studied extensively in the context of \tethered surface" m odels of polym erized mem branes [21]. By taking the nodes of the $m$ esh to coincide w ith the capsom ers, even sm allviruses can be handled in this way, although any buckling transition w ill surely be sm eared out unless $R_{b}=a$ is large, where $a$ is the spacing betw een these $m$ orphological units. Ideas from continuum elastic theory will, of course, be m ost applicable for vesicles com posed ofm any lipids and for large viruses | V inuses w ith as m any as 1692 m orphological units have been reported 22].

There $m$ ay be inherent lim itations on the size of viral capsids that follow from the elastic properties of thin shells. Because larger viruses can accom m odate m ore genetic $m$ aterial, large sizes could confer an evolutionary advantage. If, how ever, large viruses buckle aw ay from a spherical shape, the resistance of the capsid to $m$ echanicaldeform ation can degrade. A s we shallsee, a theory of buck led crystalline order on spheres also allow s estim ates of im portant $m$ acroscopic elastic param eters of the capsid shell from structural data on the shape anisotropy. E stim ates of quantities such as the bending rigidity and Young's m odulus of a em pty viral shell m ight allow an understanding of deform ations due to loading w ith D NA or RNA [4]. A though som e aspects of virus structure $m$ ay be accounted for by the physics of shell theory, we should em phasize that other features could be driven by the need for cell recognition, avoidance of im m une response, etc.

A summ ary of our investigations of buckling transitions in a spherical geom etry (discussed in detail in Sec. II) is shown in Fig.4. A s illustrated in Fig. 4] (See also Fig.50 icosahedral shells do indeed becom e aspherical as the \Foppl-von K arm an number" $=Y \mathrm{R}^{2}=$ increases from values of order unity to $Y R^{2}=\quad 1$. The mean square \asphericity" (deviation from a perfect sphericalshape) departs signi cantly from zero when $Y R^{2}=$ exceeds 154, the location of the buckling transition in at space [13]. Fits of buckled viruses or crystalline vesicles to th is universal curve would allow an experim entaldeterm ination of the ratio $Y=$. M ore quantitative inform ation on the buckled shape can be obtained by expanding the radius R ( ; ) in spherical harm onics,
and studying the rotationally invariant quadratic invariants allow ed for viruses or vesicles w ith icosahedral sym m etry, nam ely
with $\left.{ }^{\prime}=0 ; 6 ; 10 ; 12 ; 16 ; 18 ; 23\right]$. [A though any pa-

FIG.4: $\quad M$ ean square asphericity as a function of $Y R^{2}=$ for $m$ any di erent icosahedral shells. The inset show $s$ a $(6,6)$ structure w ith Foppl-von K arm an number $=\mathrm{YR}^{2}=400$. $T$ he arrow $m$ arks the location of the buckling transition in at space.
ram eter set of the form $\mathrm{fQ}_{6} \hat{i}_{10} \hat{Q}_{12} \quad \hat{Q}_{12} \quad \mathrm{~g}$ could be consistent w ith an icosahedralsym $m$ etry, allbuckled ob jects describable by the theory of elastic shells in fact lie on a universal curve param etrized by the value of $Y \mathrm{R}^{2}=$. Deviations from this curve would presum ably describe biological features such as the protrusions of the adenovinus in F ig. 2.

In Sec. II, we describe our theoretical results for disclination buckling in the icosadeltahedral spherical shells proposed by $C$ aspar and $K$ lug as m odels of vinuses [7]. The energy, m ean-square aspherity, and spherical har$m$ onic content of these shells are determ ined as a function of the Fopplvon K arm an num ber, discussed above,

$$
\begin{equation*}
=Y R^{2}=: \tag{7}
\end{equation*}
$$

M ost vinuses have either Foppl-von K am an num ber 150 (im plying a close to spherical shape) or 200 . 1500 (noticeably buckled). H igher von K arm an num bers describing ob jects w ith very shanp comers cannot be obtained for vinuses w ith $R .0 .2 \mathrm{~m}$ com posed of nite size proteins. O f course, very high von $K$ arm an num bers are possible for spherical vesicles w ith crystalline order com posed ofm uch sm aller lipid m olecules [19, 20].

W e have studied the scaling of the curvature $C$ at the creases form ed after the shells buckle for large. W e eventually recover the scaling proposed and studied in other geom etries by Lobkovsky, W itten and collaborators [16, 17], but only for very large , 10, appropriate for the buckled icosahedral vesicles described in Ref. [20].

In Sec. III, we discuiss brie y the relevance of our w ork to icosahedral viruses from the library of those whose structures have been determ ined by di raction $m$ ethods or by cryro-electron m icroscopy [1, 2, 3, 9]. For viruses
large enough to buckle, the m odel seem s to account well for the deviation from the spherical shape using the single adjustable param eter. These ts in tum provide in form ation about the ratio $Y=$ of the $Y$ oung's m odulus to the bending rigidity. W e also discuss the possible relevance of spontaneous curvature term s and outw ard pressure induced by packaged DNA and RNA in this Section. See R ef. [24] for a discussion ofsim ilar issues for the shapes of liquid $m$ em branes $w$ ith a spherical topology.

## II. DEFECTSON CURVED SURFACES

Topologicaldefects play a very im portant role in crystalline $m$ atter. A particularly com $m$ on type of defect, the dislocation, is largely responsible for the strength of m aterials, and in two-dim ensional system s the unbinding of dislocations $m$ ay drive the crystal into a hexatic phase [25]. D isclinations on the other hand, are much less com m on in the crystalline phase because of their very large energy. In quasi-tw o-dim ensional curved surfaces, how ever, the situation $m$ ay be quite di erent. T he $G$ aussian curvature of the surface will \screen" out the strain around the defect and thus low er the energy. M oreover, when a crystalline surface is bent to form a closed surface w ith spherical topology, defects are necessarily introduced into the lattice. For a triangular lattice on a sphere the num ber of disclinations has to be at least 12. $M$ ore generally, the di erence $N_{5} \quad N_{7}$ betw een the num ber of vefold disclinations and the num ber of seven fold disclinations (assum ing defects $w$ th coordination num bers other than 5 , 6 or 7 are absent) is precisely 6 tim es the Euler characteristic of the triangulated surface, i.e., $N_{5} \quad N_{7}=6=12(1 \quad g)$, where $g$ is the genus or num ber of handles. Thus for shapes such that $g=0$ (the sphere) and torii w ith extra handles ( $g$ 2), the ground state m ust necessarily contain disclinations. (A simple torus has genus $g=1$, so there is no topological necessity for defects.)

In this section we study closed surfaces of spherical topology. The 12 disclinations present in the crystalline lattice structure can be expected to dom inate the energetics and a ect the overall shape of the structure. $T$ he repulsive interaction betw een the 12 disclinations w ill favor an arrangem ent $w$ hich $m$ axim izes their separation. A bsent an instability tow ard grain boundaries [15], this leads to a con guration $w$ th icosahedral sym $m$ etry, where the disclinations sit at the vertioes. $W$ e show below that, as a result of com petition betw een strain and bending energies, these structuresm ay undergo a buck ling-like transition (sm eared by nite size e ects) from a sm ooth round shape to a sharply faceted shape as the size or elastic constants are varied.
A. D isclination Buckling on Spheres

W e assum e a thin shell described by a continuum elastic theory, w ith energy $H=H_{s}+\mathrm{H}_{\mathrm{b}}$ [5], including both an in-plane stretching energy,

$$
\begin{equation*}
H_{s}=\frac{1}{2}^{Z} d S 2 u_{i j}^{2}+u_{k k}^{2} ; \tag{8}
\end{equation*}
$$

$w$ here $u_{i j}$ is the strain tensor, and are the 2D Lame coe cients, and a bending energy,

$$
\begin{equation*}
\mathrm{H}_{\mathrm{b}}=\frac{1}{2}^{\mathrm{Z}} \mathrm{dS} \quad \mathrm{H}^{2}+2_{\mathrm{G}} \mathrm{~K} \text {; } \tag{9}
\end{equation*}
$$

where is the bending rigidity, $G$ the $G$ aussian rigidity, $H$ and $K$ the $m$ ean and $G$ aussian curvatures, respectively. (If $\mathrm{R}_{1}$ and $\mathrm{R}_{2}$ are the principal radii of curvature, $H=1=R_{1}+1=R_{2}$ and $K=1=R_{1} R_{2}$ [5].) For a closed surface w th xed topology the $G$ aussian curvature integrates to a constant (provided that $G$ is constant) and w ill henceforth be dropped, as it will have no in uence on the shape. Instead of the Lam e coe cients we w ill use the 2D Young's modulus $Y$ and the Poisson ratio , which are given by

$$
\begin{equation*}
Y=\frac{4(+)}{2+} ; \quad=\frac{}{2+}: \tag{10}
\end{equation*}
$$

Taking the variation of w th respect to coordinates param eterizing the surface leads to the Foppl-von K arm an equations which are highly nonlinear and whose solution even in sim ple geom etries is very di cult [5].

The energy ofdisclinations on exible crystallinem em branes was studied by Seung and $N$ elson in Ref. [13]. A s discussed in the Introduction, for a thin at plate of nite radius $R$ w ith an isolated 5-fold disclination at the center, the energy grow s quadratically $w$ th the radius, $E$ at ' $A Y R^{2}$, where A $=288$ is a num erical constant. If the disclination is allowed to buckle out of the plane this energy is reduced, and grows logarithm ically for large $R \mathrm{w}$ th a coe cient proportional to. In the inextensionallim it $Y$ ! 1 the problem simpli esconsiderably and the energy is $E_{\text {buckled }}$ ' $B \ln (R=a)$, where B $\quad=3$ and a the lattioe constant. Thus, for sm all plates the at solution is lower in energy, whereas for large plates the buckled solution w ins. A n instability separating these two regim es occurs when E at Ebuckled, or $Y R^{2}=\quad B=A$. A detailed calculation in $R$ ef. I3] found the transition at a critical value of $\mathrm{Y}^{2}=154$.
$T$ he spherical shapes of icosahedral sym $m$ etry we are interested in here can approxim ately be thought of as being com posed of 12 disclinations, and should therefore undergo a sim ilar transition from at to buckled. B ecause the surface of the sphere is already curved, and hence breaks the up-dow $n$ sym $m$ etry that w as present for a thin plate, it is not clear that a sharp instability survives in this case. H ow ever, even if this is the case, we $m$ ight still expect to see rem nants of the transition in the form of a shanp if not singular crossover. W e construct
below sim ple estim ates of the energies and transitions involved.

T he total energy of the closed shell in the vicinity of the transition is approxim ately 12 tim es the energy of a disclination ( $w$ ith radius approxim ately equal to the radius of the sphere), plus contributions from the background curvature of a sphere, given approxim ately by $8+4 \mathrm{G}$. In the inextensionallim it the short distance cuto in the buckled disclination energy was provided by the lattice constant. For nite $Y$ the cuto is determ ined instead by a balance of strain and bending. $W$ e $m$ ay in this case approxim ate the buckled disclination by a at inner region $r<R_{b}$ w th energy $A Y R_{b}^{2}$ and an outer buckled region $r>R_{b}$ with energy $B \quad \ln \left(R=R_{b}\right)$. M ini$m$ izing the sum $w$ ith respect to $R_{b}$ gives $Y R_{b}^{2}=B=2 A$, and $E$, $B \frac{1}{2}+\ln \left(R=R_{b}\right)$.

Because the disclination energy is independent of the tw o-dim ensional Poisson ratio and the G aussian rigid-止 drops out, the solution depends only on a single dim ensionless param eter, $\quad=Y R^{2}=$, which we term the Foppl-von K arm an number. N ote that, if the 2D elastic theory derives from a thin shell of nite thickness d built from a 3D isotropic elastic medium, we have $=121{ }_{3}^{2}(\mathrm{R}=\mathrm{d})^{2}$, where 3 is the threedim ensional Poisson ratio, a result independent of the 3D Young'sm odulus $Y_{3}$ [b]. In sum $m$ ary, we then expect the energy of the closed shellw ith tw elve disclinations to approxim ately be

$$
\begin{array}{ll}
\mathrm{E}, & 6 \mathrm{~B}=\mathrm{b}+\mathrm{D} ;  \tag{11}\\
6 \mathrm{~B}\left(1+\ln \left(={ }_{\mathrm{b}}\right)\right)+\mathrm{D} ; & >\mathrm{b} \\
\mathrm{~b}
\end{array} ;
$$

where $b=Y R_{b}^{2}=$. The background curvature gives a constant contribution D $4 \quad\left(2+{ }_{G}=\right)$, leading as well to a sm allshift in the disclination energies and hence in A and B.For a perfect sphere, e.g., 12A $0: 604=36$ [I5].

A s the disclinations becom e $m$ ore sharply buckled the whole structure will becom e m ore faceted. This leads to the form ation of ridges connecting the vertices of the icosahedron. The energy of sim ilar ridges has been studied recently [16, 17], uncovering som e rem arkable scaling relations. As the ridges becom e sharper upon increasing, the energy will increase as $E_{\text {ridge }}=$ $1: 24^{7=3} Y L^{2}={ }^{1=6}$, where is the angle in radians and $L$ is the length of the ridge. In this regim e the shape is very close to an icosahedron $w$ th sharp facets, $w$ ith $0: 365$ and L $1: 23 R$, and a total of 30 ridges. In the lim it of very large $=Y R^{2}=$ the energy should therefore crossover to

$$
\begin{equation*}
\mathrm{E}=\text {, } \mathrm{C}^{1=6}+\text { const:; ! } 1 \text {; } \tag{12}
\end{equation*}
$$

where C 3:8.
To check these argum ents and to calculate m ore properties of the shells we now present num ericalcalculations.

FIG. 5: $N$ um erically calculated shapes with $(h ; k)$ indices $(2,2),(4,4),(6,6)$, and $(8,8)$ for $x e d \sim=0.25$, and xed spring constant $=1$. The Foppl-von K arm an numbers for these shapes are $45,176,393$ and 694.

B . N um erical R esults

For num erical calculations it is useful to consider discretized versions of Eqs. (8) and (9) [13]:

$$
\begin{equation*}
H_{s}=\frac{-}{2}_{\text {hiji }}^{X} \quad\left(\dot{j}_{i} \quad r_{j} j \quad a\right)^{2} \tag{13}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{H}_{\mathrm{b}}=\frac{\sim}{2}_{\mathrm{hIJi}}^{\mathrm{X}}\left(\mathrm{~A}_{\mathrm{I}} \quad \hat{\mathrm{n}}_{\mathrm{J}}\right)^{2}: \tag{14}
\end{equation*}
$$

H ere hiji denote pairs ofnearest neighbor vertices (w hich we identify w th the centers of the capsom ers of a virus), w th positions $r_{i}$, and hIJ i pairs of nearest neighbor plaquettes of a triangulated surface, $w$ ith unit norm als $\mathrm{f}_{\mathrm{I}}$. In the continuum lim it this $m$ odelbecom es equivalent to Eqs. (8) and (9) w ith param eters (13]

$$
\begin{align*}
Y & =\frac{P_{\overline{3}}^{3}}{} ; & & =\frac{1}{3}  \tag{15}\\
& =\frac{P^{3}}{2} \sim ; & G & =\frac{4}{3} \tag{16}
\end{align*}
$$

The relation $G=4=3 \mathrm{w}$ as calculated by com paring the bending energy of a triangulated cylinder and sphere w ith the corresponding continuum expressions, and differs from the one used in Ref. [13]. C losed triangular surfaces of icosahedralsym $m$ etry are constructed fornonnegative integers ( $h ; k$ ) according to the geom etric principles of $C$ aspar and $K \operatorname{lng}[$ ], and the $m$ inim um energy

F IG . 6: Total energy. D otted and dashed lines are ts to Eq. (11) and (12), respectively. T he arrow indicates the value of $b$ obtained from the $t$.
con guration is found num erically using a con jugate gradient $m$ ethod for di erent values of $\sim$. A s discussed in the Introduction, the integers ( $h$; $k$ ) denote the num ber of steps along the tw o lattice vectors betw een tw o neighboring disclinations of the structure. $F$ igure 5 show s som e exam ples of the resulting shapes. Shapes of varying size with \T -num bers" as large as $T=h^{2}+h k+k^{2} \quad 1500$ are studied. Below we calculate som e properties of the shells to characterize the shapes quantitatively.

## 1. Energy

W e rstplot the totalenergy as a function ofthe Fopplvon K arm an num ber in F ig. (6. Sim ilar to results for an isolated disclination in a disk with free boundary conditions [13], the energy crosses over from a $\backslash$ at" regim e dom inated by stretching energy to a \buckled" regim e dom inated by bending energies. Fitting the functional form Eq. (11) gives A $0: 005$, B $1: 30$, b 130, which com pares quite wellw ith the estim ates above. For large \& $10^{7}$ a crossover to the form given by Eq. (12) (indicated by the dashed line in the gure) occurs.

## 2. A spherity

A s a m easure of the deviation from a perfectly spherical shape centered on the origin we calculate the $m$ ean squared aspherity, de ned by

$$
\begin{equation*}
\frac{R^{2}}{h R^{2}}=\frac{1}{N}_{i=1}^{X^{N}} \frac{\left(R_{i} h R i\right)^{2}}{h R i^{2}} \tag{17}
\end{equation*}
$$

FIG.7: M ean squared aspherity (see Eq. (17) as a function of $=Y R^{2}=$ for various \triangulation numbers" $T=h^{2}+$ $h k+k^{2}$. D ata from shapes of three di erent sizes collapse onto a single universal curve, indicating that the continuum lim it has been reached for these sizes.
$w$ here $R_{i}$ is the radial distance of vertex $i$ and $h R i$ is the m ean radius,

$$
\begin{equation*}
h R i=\frac{1}{N}_{i=1}^{X N} R_{i}: \tag{18}
\end{equation*}
$$

T he result, which is displayed in Fig. 7 , show s a rather shanp, but non-singular crossover from spherical shape to faceted at roughly $=\mathrm{YR}^{2}=$ 150. The second increase around $Y R^{2}=\quad 10$ coincides roughly $w$ ith the sharpening of the ridges, w here the asym ptotic scaling in Eq. (12) sets in. N ote that the log-linear plot of F ig. 7 extends the range of in F ig. (4) by six orders of m agnitude.

## 3. Icosahedral spherical harm on ics

W e rst expand the radial density of points on the surface in spherical harm onics,

$$
\begin{equation*}
\mathrm{R}(;)=\mathrm{X}_{\mathrm{l} ; \mathrm{m}}^{\mathrm{X}} \mathrm{Q}_{\mathrm{lm}} \mathrm{Y}_{\mathrm{lm}}(;) ; \tag{19}
\end{equation*}
$$

where the density $\mathrm{R}(\mathrm{i})$ is de ned by

$$
\begin{equation*}
R(;)={ }_{j}^{X} R_{j}(\quad j) \quad\left(\cos \quad \cos _{j}\right) ; \tag{20}
\end{equation*}
$$

and $\left(R_{j} ; j ; j\right)$ represents the polar coordinates of vertex $j$. From the coe cients $Q \mathrm{~lm}$, we form the rotationinvariant com binations

$$
\begin{equation*}

F IG . 8: C om bination of sphericalharm onics (see text), which fall on a universal curve for large enough shells. P oints for triangulations de ned by $(h ; 0) ; h=5 ; 6 ;::: ; 25$ were used to construct the solid curve. For $h<5$ deviations due to discreteness becom e large and those points have been om itted for clarity. Points labeled $1\{6$ correspond to $0: 5 ; 30 ; 1000 ; 15000 ; 8 \quad 10^{6}$ and $2: 5 \quad 10^{8}$, respectively.

For a shape of icosahedral sym $m$ etry the $Q_{1}$ 's are nonzero only for $l=0 ; 6 ; 10 ;:::$ [23]. W e plot, in $F$ ig. 8 , $\mathrm{Q}_{10}=\mathrm{Q}_{0}$ vs $\mathrm{Q}_{6}=\mathrm{Q}_{0}$, which for large shells should fall on a universal curve param eterized by $Y R^{2}=$. $N$ ote that any point in the ( $\mathrm{Q}_{6}=\mathrm{Q}_{0} ; \mathrm{Q}_{10}=\mathrm{Q}_{0}$ )-plane would be consistent w ith an icosahedral sym $m$ etry. Continuum elastic theory, how ever, predicts a universal set of functions $Q_{1}($ ) param etrized only by the Foppl-von K arm an num ber. The buckling transition occurs betw een the points labeled $2\{4$ in F ig. 8 , while the crossover to the ridge scaling for very large happens between points $4\{6$.

## 4. C urvature

The curvature $C$ across them idpoints of the ridges connecting the vertices of the icosahedra is plotted in F ig. 9 . As $=Y R^{2}=$ increases through the transition the ridges get shanper and the shape becom es $m$ ore faceted. A perfect sphere would have $C=1=R$. H ow ever, as seen in Fig. [9, C R saturates to a slightly sm aller value,' $0: 7$, for very $s m$ all , im plying that the shape is not perfectly sphericalbelow the buckling transition. In fact, there is a weak tendency tow ard a dodecahedral shape (which is the dual to the icosahedron). T he e ect is hardly visible (cf. Fig.7), how ever. T he data for large shells is well described by a scaling form

$$
\begin{equation*}
C=R \quad{ }^{1} F\left(Y R^{2}=\right) ; \tag{22}
\end{equation*}
$$

depending on the single param eter. In the lim it of large argum ents ! 1 , we nd F ( ) ! ${ }^{1=6}$, consistent $w$ th

F IG . 9: C urvature at them idpoints of the ridges. The points labeled 1 \{ 6 are for the sam $e$ values of as in $F$ ig. 8 . The dashed line show s the asym ptotic scaling behavior ${ }^{1=6}$.
the scaling argum ents of Lobkovsky et al. [16, 17]. N ote, how ever, that 's wellin excess of $10^{6}$ are required before one begins to see this asym ptotic result of $\backslash$ ridge scaling" .

## III. D ISC U SSIO N

W e have analyzed a m odel, based on the (highly nonlinear) physics of thin elastic shells, which $m$ ay be suitable for describing the shapes of large viruses and of large vesicles w ith crystalline order in the lipids. A pplication of our results to vesicles [19, 20] seem s straightforw ard, once su ciently precise freeze fracture or confocal microscope in ages becom e available. F igure 10 illustrates tw o highly faceted shapes we found for the large Fopplvon $K$ arm an num bers or \vK 's" which $m$ ight be relevant to the experim ents of $R$ ef. [20]. O ne com plication neglected here concems possible phase separation of the binary lipid $m$ ixtures studied by D ubois et al in the vicinity of the 12 disclinations [20]. It would be interesting to investigate this e ect, although a m odest en richm ent of one lipid species near a disclination could be inconporated into a renorm alized core energy. A s discussed in Sec. IIB, vK 's in excess of $10^{6}$ are required to see clearly the interesting scaling predictions of Refs . [16] and [17]. In the rem ainder of this section, we com $m$ ent on the relevance of our work to spherical viruses [1, [3, 7, [9], where the vK's are of order a few thousand or less.

Ref. [3] com piles cryro-electron $m$ icrographs and other data on approxim ately thirty di erent viruses, arranged in order of increasing size. T hese im ages highlight the trend that sm all viruses are round and larger viruses are $m$ ore faceted. We view faceted viruses as the result of 12 sim ultaneous buck ling transitions, centered on

FIG. 10: Two shapes for the large Foppl-von K arm an num bers $=15600$ and $8 \quad 10^{6}$ (points 4 and 5 in F ig. 8.9), illustrating the sharpening of the ridges in the ridge scaling regím e.

12 disclinations, sim ilar to the buckling of an isolated disclination centered on a disk with open boundary conditions [13]. The spherical packing of the protein capsom ers in viruses not only forces in twelve disclinations (which we assume reside at the vertices of an icosahedron) [7], but also breaks the up/down sym $m$ etry of a disk with respect to the direction of buckling. Hence, we expect (and nd num erically) that the sharp buckling transition w ith increasing size in Ref. [13] is sm eared out. A s shown in Fig. 11 for bacteriophage HK 97 (w ith 72 capsom ers), good one param eter ts in real space to the full three dim ensional shape of spherical viruses are possible. O ur best $t$ for Foppl-von K am an number of this mature form of HK 97 is $=Y R^{2}==1480$, from which we can extract the ratio of the $Y$ oung's m odulus $Y$ to the bending rigidity, given that the virus diam eter is $2 R=60 \mathrm{~nm}$ [3]. The precursor capsid or $\backslash$ prohead" of HK 97 is rather spherical, in contrast to the larger, m ore faceted $m$ ature infectious virus show $n$ in $F$ ig. [11 [27]. It seem s likely that this virus particle undergoes a buckling transition as it passes from the prohead to its m ature infectious form. Indeed, the prohead shell is wrinkled or corrugated relative to the $m$ ature form [27]. It seem $s$ reasonable to regard this transform ation as a change in the e ective thickness $d$ of the viral shell: $d^{0}$ of the prohead goes to $d<d^{0}$ in the $m$ ature form. A s discussed in Sec. IIA, $=12\left(\begin{array}{ll}1 & { }_{3}^{2}\end{array}\right)(R=d)^{2}$ if we approxim ate the shell.by a uniform isotropic elastic $m$ edium $w$ ith P oisson ratio 3 [5]. Since $2 R$ increases from $52 \mathrm{~nm}!60 \mathrm{~nm}$ as $d$ decreases, it is plausible that $\quad\left(R=d^{\gamma}\right.$ rises and that the transform ation from prohead! head is accom panied by a buckling transition.
$F$ igure 12 show $s$ a sim ilar $t$ to the yeast $L-A$ vinus, which yields $=Y R^{2}==547$. The diam eter of the yeast virus is $2 R=43 \mathrm{~nm}$, which leads to the conclusion
 1:64 nm ${ }^{2}$, consistent w ith the argum ents given in the Introduction that spherical viruses have roughly sim ilar elastic constants.

O ur m odels for virus shells are based on two im portant assum ptions. The rst is the neglect of a spontaneous curvature term [26] in bending energies such as Eq. 9. Such a term $m$ ight be signi cant if the viralbuild-
ing blocks had a pronounced conical shape sim ilar to, say, surfactant m olecules in a m icelle [26, 28] or laboratory cork stoppers. Several lines of evidence suggest that neglect of this term m ight be justi ed. A though certain virus sca olding proteins (which can act as tem plates for early phases of construction) do have a conical shape, these are discarded in the $m$ ature icosahedral viruses of interest to us here [1]. It is hard to see a strong $m$ echanism forprecisely-de ned hinge angles in very large viruses com posed of $m$ any capsom ens [29, 30]. In vitro assem bly experim ents on the polyom a virus do produce sphericalaggregates w ith 12,24 and 72 pentam eric units depending on conditions of pH , calcium concentration, etc [31], which could be accounted for by a spontaneous curvature term. A lthough we neglect spontaneous curvature here, it is certainly possible that the physics of sm all viruses (or the sca olding proteins them selves) are in uenced by such an energy, as has been explored by B ruinsm a, R udnick and Gelbart [32].

In general our work is m ore likely to be applicable to large viruses, for which sim ple continuum $m$ odels can be justi ed. Icosahedral viruses are usually com posed of a combination of 5-and 6-fold sym $m$ etric packing units, $w$ ith the twelve 5-fild units centered on the vertices of an icosahedron (the polyom a virus SV 40 [3] w ith its 72 identical pentam ers is an exception). Because the strain energies w hich lead to buckling extend far from the disclinations which produce them [13], we would expect our results for large viruses to be insensitive to di erences in the shapes of packing elem ents. Special packing elem ents at the twelve 5-fold sites could be inconporated into a disclination core energy.

A second key assum ption is our neglect of the osm otic pressure due to the con ned DNA orRNA package of the virus [4]. H ere we can appeal to an experim ent. Eamshaw and H arrison [33] have com pared the structure of phage lam bda (P 22) w ith its full com plem ent of D NA to the structure of lam bda m utants containing only 78\% of the native DNA. A lthough changes in the details of DNA packing can be detected, the protein shell itself is unchanged. Thus, due either to DNA condensation or an exceptionally strong shell, the osm otic pressure of the DNA is insu cient to change the shape. Of course, the nucleic acid content of a virus could nevertheless play an im portant role in shell assem bly [34].

## A cknow ledgm ents

It is a pleasure to acknow ledge valuable advioe and conversationsw ith S.H arrison, B. Shraim an, J. Johnson, S. Burley, R.Bruinsm a, P. Lenz, J. Israelachvilli, and T. Zemb.
