# M esoscopic M echanics

A rtur Sowa 109 Snowcrest Trail, Durham, NC 27707 www.mesoscopia.com

#### Abstract

This article is concerned with the existence, status and description of the so-called emergent phenom ena believed to occur in certain principally planar electronic system s. In fact, two distinctly di erent if inseparable tasks are accomplished. First, a rigorous mathematical model is proposed of emergent character, which is conceptually bonded with Q uantum M echanics while apparently non-derivable from the many-body Schrodinger equation. I call the resulting conceptual fram ework the M esoscopic M echanics (M eM). Its form ulation is spaceindependent and comprises a nonlinear and holistic extension of the free electron model. Secondly, the question of relevancy of the proposed \emergent m echanics" to the actually observed phenom ena is discussed. In particular, I postulate a probabilistic interpretation, and indicate how the theory could be applied and veri ed by experiment.

The M esoscopic M echanics proposed here has been deduced from the N onlinear M axwell Theory (NMT) a classical in character nonlinear eld theory. This latter theory has already been shown to provide a consistent phenom enological m odel of such phenom ena as superconductivity, charge stripes, m agnetic vortex lattice, and m agnetic oscillations. The NMT, which arose from geometric considerations, has long been awaiting an explanation as to its ties with the fundam ental principles. I believe the M eM provides at least a partial explanation to this e ect.

This work has been presented in part at the International Sym posium on Inhom ogeneous and Strongly Correlated M aterials with N ovel E lectronic P roperties (ISCM), held at M iam i B each FL (USA) as a part of the SM EC m eeting, during M arch 24-28, 2003.

# 1 The incentive to consider em ergent m athem atical structures

The article [3] by R.B. Laughlin and D avid P ines inspires us to re-exam ine the status of the reductionist paradigm, and perhaps also the basic assum ptions as to the meaning of complexity and its bearing on how we attempt to understand physical phenomena. Moreover, an even more bewildering question stands whether complexity may play a direct role in how things actually work. Stillmore disturbingly, the only meaning of the phrase \how things work" may be endowed to it by our attempt to understand how they work, and depend on its peculiarities including our choice of the paradigm. In particular, there may be several mathematically nonequivalent ways of modelling one and the same phenomenon, all true, coexisting alongside and complementing one another. Be it as it may, there is a danger of dogmatism in rejecting any possibility that there is room for emergent way of thinking and emergent mathematical models.

The beautiful and puzzling phenom ena observed in some new principally planar electronic system s based on novelm aterials invite re ection on justi ability of a functionally apt m athem atical m odel that does not exactly begin with the Schrodinger equation. Before anything else, it may be worthwhile to try and exam ine the \m athem atical reality" of this problem and ask if we can construct m athem atical m odels of clearly em ergent character at all. A m odel of this sort would have to be conceptually tied with the basic principles while in possible or prohibitively di cult to deduce from the Schrodinger equation in conjunction with the Pauli exclusion principal. These singular requirements seen quite reasonable inasmuch as they parallel our intuitive grasp of the nature of the phenom ena suspected of being em ergent. It is im possible not to mention some preexisting examples that at least come close to ful lling these requirem ents, like the classical G inzburg-Landau equation or the Solitons. Both these theories may be viewed as supplying emergent m odels, save their ties with the basic principles are in a typical application postulated rather than inherent or rigorously derived. In this sense, these classical theories are not perfect examples of emergent mathematical models.

M any m acroscopic electronic properties of 2D electron gas in a m agnetic eld depend on the following basic if som ew hat idealized and simplied picture resulting from the free electron model, which is good to keep in mind

during our discussion. Namely, as we apply perpendicular to the sample increasing magnetic eld B, the separation between Landau levels increases proportionately. As it happens, the consecutive Landau levels cross over the Ferm i level and some electrons residing at these levels are emptied while som e reoccupy a lower Landau level. This contributes directly to the conductivity of the sample. In particular, the longitudinal conductivity, as well as other m acroscopic param eters, will display oscillatory dependence on the m agnetic induction. At low tem perature, the num ber of electrons occupying each Landau level is close to the degeneracy of levels ( $N_L = eB = h$ ). As a result, som e m acroscopic param eters which depend on the total number of conduction electrons can only change in (the appropriately scaled) multiples of the degeneracy of the Landau levels. One particular e ect seem ingly related with this mechanism is known as the Quantum HallE ect (QHE), which is quantization of the transversal conductance (ratio of the longitudinal current to the transversal voltage). Not that a full explanation of the QHE is constructed with argum ents using this picture, but at least it is possible to come in touch with the QHE by using this type of reasoning. However, this mechanism alone becomes drastically insu cient as we attempt to explain the Fractional Quantum Hall E ect (FQHE). During the last two decades, researchers have proposed many new concepts and carried out a lot of calculations to explain the FQHE (e.g. cf. [2]), including com posite particle type approach to the many-body Schrodinger equation or work on the so-called localized states, or the so-called e ective eld theories. This latter development (cf. [9]) is based on the postulate that the 2D electron gasmay interact with the magnetic eld in some profoundly di erent ways than a single free electron does. In other words, in addition to the Lorentz force and Landau quantization, there may be another e ect at play which is switched on in a planar electronic system under certain conditions. I subscribe to this idea, and will propose a mechanism for exactly that via the Mesoscopic Mechanics formulated in this article. It needs to be emphasized that the mechanism described by the M eM is utterly di erent than the e ective eld theory m entioned above. This \new " mechanism of interaction does not by any means \switch o " the Landau states, whenever these are permitted to form in a m aterial, but rather it is an additional and separate e ect that needs to be considered. The de ning feature of the e ect is that it gives rise to inhom ogeneous distribution of the magnetic eld throughout the sam ple. The exact form of this e ect will be postulated and explained in Section 2.

A swewill see, the dynamic variable of the Mesoscopic Mechanics introduced below is a transform. Before anything else, I would like to point out that this by itself is nothing very unusual for several reasons. First, it seems unavoidable in this kind of work to have some sort of an object that would account for global e ects resulting from local interactions, e.g. some sort of an order parameter, and the transform postulated by the MeM fulls this exact role. A loo worth mentioning here is the classical idea that the response of a macroscopic parameter to the external eld could be viewed via the linear response model. This has been tried in the context of the Quantum HallE ects via the well-known K ubo form ula, which gives a treatment of the Hall current based on the Ansatz that it will respond linearly to the external

eld. In that approach conductivity is a multiplier an object not unlike the operator which is the dynam ic variable of the (quite nonlinear) M esoscopic M echanics. Finally, as we know scattering phenom ena may be viewed as transform s. Indeed, as the H am iltonian is perturbed and the originally distinguished basis of eigenstates is replaced by another, the whole process may be encoded in the corresponding change-of-basis transform, even if typically such a transform would not be determ ined uniquely. A question stands, can this be understood from a higher level, i.e. is there a m eta-theory that would take the transform itself as the dynam ic variable and explain its particular value as the critical point of a m eta-H am iltonian appropriate for a given scattering process? N aturally, this is a question about m athem atical structure of the physical theory rather than a problem of physics, which is not to say that it wouldn't be of interest from the purely physical standpoint. A nyhow, such a possibility is not unthinkable in general, and is interesting to m ention in the context of the M esoscopic M echanics.

Finally, I concede it may yet turn out that the phenom enon I conjecture in this article may in fact be in some way derived from the many-body Schrodinger picture. Either way, the M eM is of interest.

## 2 Form ulation of the M esoscopic M echanics

The inspiration for the formulation of M esoscopic M echanics comes from a long work on the Nonlinear M axwell Theory synoptically described in Section 5. A prominent role in that latter theory is played by the deceivingly benign logarithm ic integral  $^{\rm R}$  hf of a real function f. Remarkably, this ex-

pression has the meaning of the logarithm of the determ inant of the operator of multiplication by f. Indeed, using the integral seems to be the only correct way to re-norm alize an otherwise divergent expression and make sense of the determ inant of this operator. This algebraic object is in turn related to the entropy associated with an operator. Entropy has yet another description as the logarithm of the corresponding partition function, say,

$$\log^{2} \mathbb{D}' \exp\left(\frac{1}{2}hK';K'i\right)$$
(1)

Strictly speaking, this is the entropy associated with the operator K K rather than K itself. This ubiquitous in the Q uantum Field Theory integral over the in nite-dimensional space is understood in any way suitable and will cause no essential technical di culties in the context of our discussion.

W e now turn attention to an idealized planar electronic system exposed to the perpendicular magnetic eld with magnetic induction B.W e om it the appropriate constants, but adopt the convention that B<sup>2</sup> is measured in units of energy. Suppose the electronic system is characterized by the single-particle Ham iltonian H whose exact nature is not speci ed a priori. For example, H could incorporate a periodic potential resulting in the Bloch states, or it could be the Landau Ham iltonian resulting in the Landau states, or it could incorporate impurity potentials possibly leading to localized states, etc.

To steer the discussion away from m athem atical technicalities, let us assume that the H am iltonian H has a discrete spectrum. Let  $j_n i$  denote the complete set of states with the corresponding eigenvalues  $E_n$ , so that

$$H j_n i = E_n j_n i:$$
 (2)

Here, the index n is not a physical quantum number but a label indexing the eigenstates, with the convenient proviso that the corresponding energy E  $_n$  is a nondecreasing function of n.

Now, we introduce the complete H am iltonian % f(x) = 0 whose arguments are operators denoted K . It is denoted as follows

$$(K) = trace (K H K) + B2 log det (K K)$$
(3)

Here det denotes the determ inant of the nondegenerate part, i.e. the product of all nonzero eigenvalues accounting for their multiplicities. In fact, without loss of generality, as it turns out a posteriori, we may assume that

is an operator with null kernel, kerK = f O g; whose domain F and target space G = Im (K) are nite-dimensional subspaces of span<sub>L2</sub> fj ni: all ng. D isregarding som e constants, the second term on the right-hand side is regarded as essentially identical with the entropy (1). It is intuitively appealing to say that the rst term of the Hamiltonian is responsible for a singleelectron portion of the energy, while the entropy term accounts for the energy of inter-electron interaction. The interaction is switched on with an application of the magnetic induction. It may be facilitated by elds of a predeterm ined character whose actual nature does not a ect the theory in any way. Yet one may try and consider some more concrete scenarios, e.g. the elds ' in (1) could represent phonons, charge-waves, or spin-waves. As a matter of fact, this last possibility would require a spin-form ulation of the theory which will be brie y addressed later. Finally, I do not exclude the possibility that the Hamiltonian expresses an emergent fundam ental law, ie. that this is how electron gas interacts with the ambient magnetic eld even in the absence of any additional structures, e.g. even in the absence of the containing crystal lattice if it were at all feasible. A swe will see, the entropy interpretation of the second part of goes hand in hand with the probabilistic interpretation of K K postulated below. Naturally, the model is more general than any single underlying physical system and there may be other applications and interpretations.

Let us consider extrem a of the functional (3) subject to the constraint

A direct calculation shows that the critical points satisfy the Euler-Lagrange equation in the form

$$K H + B^{2} (K)^{1} = K :$$
 (4)

[The reader who carries out the calculation will see that there is also another equation, equivalent to this one via conjugation.] It follows that

$$K K = \frac{B^2}{H j_{H <}};$$
 (5)

where the restriction  $j_{i}$  denotes the orthogonal projection to the subspace spanned by the eigenfunctions of H corresponding to the eigenvalues strictly

less than . Therefore, any two solutions K di er by a unitary transform ation, say, U , and the general solution has the form

$$K = U \frac{B}{(H j_{H < 1})^{1=2}};$$
 (6)

or more explicitly

$$K = U \qquad \frac{X}{E_{n} < \frac{B}{(E_{n})^{1=2}}} j_{n} ih_{n} j;$$
(7)

where

 $U : F ! G ; U^{1} = U$ 

is a unitary operator whose dom ain is

$$F = fH < g = spanfj_n i:E_n < g:$$
 (8)

The space F is interpreted as the Ferm i sea at T = 0 and remains xed at all times. On the other hand, the target space G is a priori unspecied. It has to be emphasized that

is dim ensionless.

It is perhaps worth pointing out that setting B = 0 in the equation (4) forces to become an eigenvalue and K a generalized eigenstate K =

, i.e. an orthogonal projection onto the space spanned by all eigenstates corresponding to the eigenvalue . It is remarkable that since the solution K in (6) depends algebraically on the Ham iltonian H, all essential analytical di culties are concealed in the treatment of the linear operator H. This gives us total freedom in the choice of the type of problem we want to consider, e.g. a boundary value problem, etc.

W ith the basic notions already in place, it is clear that we have entered the dom ain of a new paradigm and there could be no interpretation of K and

within the fram ework of a preexisting theory. This venture is here seen as necessary in order to understand som e em ergent phenom ena encountered in planar electronic system s. To be sure, the H am iltonian has been concocted with the fam iliar elements of Q uantum M echanics and the Q uantum Field Theory. It is only the relation of the operator K to the physical system that needs to be postulated. W ith this understood, I will now put forward som e ways of interpreting the model. The emerging new paradigm is in harm ony with the principles of Q uantum M echanics, accepting and building upon its interpretation and postulates. However, the interpretation of M esoscopic M echanics requires new postulates that are extrinsic to Q uantum M echanics.

First Postulate of the M eM : Suppose a magnetic eld with magnetic induction B  $\stackrel{\bullet}{\bullet}$  0 is applied transversally to a two-dimensional electron gas. Then, for an (\electronic") statistical state W there is a corresponding (\magnetic") state K W K , where K is a critical point of the H am iltonian (3) given in (6) and (7). It is postulated that an observable A representing a measurement of the magnetic eld or its electron has the expectation

$$hAi = \frac{\text{trace}(AKWK)}{\text{trace}(KWK)}:$$
(9)

Observe that since the new state KWK can be normalized, e.g. so as to guarantee

$$trace(KWK) = 1;$$

it is in fact independent of the value of B as long as B  $\pounds$  0.0 bserve that only the below Ferm ipart of the input state W a exts the output state K W K .

We obtain an interesting example by applying this transform to the temperature-T Fermi state

$$S = \begin{bmatrix} z \\ f(E;T) \end{bmatrix}_{E} \begin{bmatrix} p \\ E \\ dE; \end{bmatrix}$$

where

$$f(E;T) = 1 = (exp \frac{E}{kT} + 1)$$

is the Ferm idistribution with Ferm ienergy , and  $_{\rm E}$  denotes the orthogonal projection on the space spanned by all the eigenstates of the Ham iltonian with eigenvalue E. The corresponding magnetic state (before norm alization) will be 0 - 1

$$KSK = U {}^{0}B^{2} {}^{Z} \frac{f(E;T)}{E} {}^{p} \frac{p}{E} dE^{A} U;$$

C onsider in particular the state  $W = I j_{i < c}$  related to absolute zero tem perature. In this case the magnetic state is

$$K K = U \qquad X \qquad \frac{B^2}{E_n} j_n ih_n j U :$$

Suppose for a moment that  $U = Ij_{i<}$ . Heuristically, we say that the respective probability of nding a magnetic ux quantum in residence on the state  $j_n$  ih  $_n$  j is equal to

$$\frac{1}{\text{trace (K K )}} \quad \frac{B^2}{E_n}:$$

Consider another example in which U consists in switching two states, say, j<sub>k</sub>i and j<sub>l</sub>i and acts as identity on the space spanned by the remaining states, i.e. x

$$U = \int_{n \neq k:l}^{n} j_n ih_n j + j_k ih_l j + j_l ih_k j$$

In this case

$$K K = \frac{X}{n \in k; 1} \frac{B^2}{E_n} j_n ih_n j + \frac{B^2}{E_k} j_1 ih_1 j + \frac{B^2}{E_1} j_k ih_k j;$$

i.e. we observe switching of the corresponding probabilities of nding the magnetic ux quanta in residence on states  $j_k$  ih  $_k$  j and  $j_1$  ih  $_1$  j. This underscores the importance of understanding how U may be allowed to evolve in time and depend on parameters, which will be discussed in Sections 3 and 4. It seems tempting to think of

$$\frac{1}{\text{trace}(K K)} = \frac{B^2}{E_n} j_n ih_n j$$

as a sort of elementary excitation as in, say, a G edanken experiment in which the n'th electron evaporates above the Ferm i level carrying away the corresponding fraction of the ux. One needs to keep in m ind the probabilistic interpretation as well as the fact that this type of evolution can only be realized via the corresponding evolution of the transform U.

Let K be a singular point of the H am iltonian . It is interesting to observe that the spectral characteristic of the m agnetic state form ed via the transform

is mainly determined by the electrons under the Fermi surface. The magnetic state ism one than merely a virtual construction. In fact, very particular constraints are imposed on the possible outcomes of measurement of the magnetic eld, e.g. an observable which is null on the subspace G will return expected value zero in (9). Separately, one should keep in mind that the occupation of the electronic states below the Fermi level remains una ected. In particular, one should apply the electronic state in consideration of phenom – ena that are independent of the magnetic eld, as for example the screening e ects.

Since the First Postulate seem s to fully determ ine how them agnetic properties of the system depend on its state, the Second Postulate which we will now formulate is perhaps not so much necessary as it is interesting. However, we note that so far the formulation of M esoscopic M echanics has been completely space-independent, i.e. fully contained within the fram ework of operator algebra while the electronic states played only an auxiliary role. Since the theory pertains to m esoscopic-scale phenom ena after all, it would be incom plete without som e indication of what is to be expected as regards the planar distribution of, say, the magnetic ux. The Second Postulate ful-

lls this speci c function. It pertains to coherent states whose role in the m any-particle setting is less pronounced and perhaps not so well understood as their single-particle applications. A nyhow, observe that to any electronic coherent state C =  ${P \atop_n c_n j_n i}$  we can assign a magnetic ux coherent state via

$$C ! K C :$$
 (11)

Again, both C and K C may require a speci c normalization depending on an application.

Second Postulate of the M eM : Consider the coherent state

keeping in m ind that in fact it depends on the phases of eigenstates. Suppose now that a magnetic eld with m agnetic induction B  $\leftarrow$  0 is applied transversally to a two-dimensional electron gas. It is postulated that the planar concentration of the magnetic ux is characterized by the coherent ux state

к;

where K is a critical point of the H am iltonian (3) given in (7). In particular, a measurement of the surface distribution of the magnetic ux is expected to be well approximated by

where is the total magnetic ux through the surface.

Suppose for example that

$$K = B \frac{X}{E_n < \frac{\exp i'_n}{(E_n)^{1-2}}} j_n ih_n j;$$

so that here the operator U is diagonal in the basis of eigenstates. In such a case an application of the transform K results in

$$K = B \qquad \frac{X}{\text{lled states}} \frac{\exp i'_{n}}{(E_{n})^{1-2}} \quad j_{n}i: \qquad (12)$$

If we agree that in this model j j<sup>2</sup> represents a planar concentration of electron charge (which would depend on the phases of the eigenstates !) then we may view ! K as a charge-to-ux transform of sorts. The Figure shows two particular examples of the modulus function  $\frac{1}{7}$  (in arbitrary scaling) in a free 2D electron gas at zero tem perature. The elective wavelengths of the wave functions in a free electron gasm odel with periodic boundary conditions depend on the size of the sample (torus). In consequence we observe that in the correlated-phases mode, i.e. when all ' n's are equal and all the phases of the states  $j_n i$  are also equal, there is exactly one vortex on the whole torus. We observe a characteristic splitting and deform ation of this vortex into a bunch of stripes when the phase modes  $'_n$  or the phases of the states  $j_n$  is are distributed random ly. The fact not to be m issed is that here the vortices are form ed in total absence of the Landau states. In a real m aterial, the spectral properties and the average separation between the vortices would depend explicitly and very heavily on the band structure below the Ferm i surface, the particular waveform s of the corresponding electronic states, as well as the phase modes, including the ' n's. A lso, unless the Ferm i surface does not prohibit closed orbits thus suppressing form ation of Landau states, as it may be the case in a strictly two-dimensional crystal for example, one should consider the Landau Ham iltonian.

Thus, the Ham iltonian (3) together with the transforms (10) and (11) provide a fram ework for the description of a new type of interaction of the

magnetic eld with the Ferm i sea which is believed to universally occur in principally two-dimensional systems. The suggested interaction is independent and separate from the phenom enon of form ation of Landau states. Naturally, the observed e ects of this phenom enon strongly depend on the band structure of the actual material and other parameters, like tem perature but also the initial state  $U_0$  and time evolution of the unitary transform U, which is discussed in Section 3. In particular, a possibility of there being an energy gap at the Ferm i level is of consequence for the nature of the transform K. Indeed, if there is no energy gap at all, then electrons occupying states strictly below the Ferm i level will contribute only very weekly to the uxdensity state. Inform ally speaking, the probability weights  $B^2 = (E_n) \cos^2 \theta$ responding to the states from strictly below the Ferm i level will be negligibly small as compared to the in nite weights falling on those states for which . If on the other hand, an energy gap 4 separates the Ferm i level from E . ′ the occupied states, then the corresponding distribution of weights will be m ore uniform. This sensitizes the theory to all the phenom ena and m aterial properties dependent on the existence and size of the energy gap, e.g. m etalinsulator (Peierls) transition, energy gap in sem iconductors, energy gap in superconductors, etc. Naturally, the presence of an energy gap makes the theory more sensitive to the entire band structure of a given material. It is a form idable yet worthwhile task to analyze the implications of this theory in more realistic band-structure models.

The emerging picture of M eM is that of a meta-theory. The phenomena it describes result from the band-structure but do not a ect it. Strictly speaking, it is only the sub-Ferm i surface part of the band structure that is una ected as the formation of the magnetic states should typically a ect electrons with energies at the Ferm i level. We do not attempt a detailed analysis of this latter problem here. A detailed analysis of this problem, e.g. description of the behavior of a free electron in the resulting nonuniform magnetic eld would shed some light on how the phenomenon at hand may a ect the Hall e ect. The future may hold the solution of this fascinating problem.

#### 3 Time evolution

The presence of an analogy between two theories is always a nontrivialm atter as it opens the possibility that the two theories may be just di erent facets of a yet unknown unifying higher-level construction. In this section we will postulate that the already clear analogy between the M esoscopic M echanics and the Schrodinger M echanics extends to time evolution as well. First, just as the matrix U in (6) can a priori depend on a parameter, it is also free to depend on time. In view of the interpretation provided in the First Postulate of the M eM, if the system were conservative, the evolution of the state would be generated by the H am iltonian. However, our matrix U is nite dimensional and so cannot be obtained by exponentiating the in nitedimensional H am iltonian H for one thing, and moreover the system as a whole is not characterized by H. Let us observe that when

$$U = U_0 \exp(i t = h); \qquad (13)$$

then the corresponding K as in (6) is a solution of the M esoscopic Schrodinger equation

$$ihK = KHB^{2}(K)^{1}$$
 (14)

O nem ay interpret the solutions of this type as representing correlated evolution in a certain sense as explained henceforth. Indeed, equation (14) adm its other types of solutions, say, of the form

$$K = \mathop{a_n(t)}_{E_n <} a_n(t) j_n ih_n j; \qquad (15)$$

All we need to guarantee is that all the  $a_n$  satisfy the ordinary di erential equation

$$iha_n = E_n a_n = \frac{B^2}{a_n}$$

W riting  $a_n = r_n e^{i' n}$ , plugging it into the equation above and separating the real and in aginary parts we obtain

$$r_n = 0$$
 and  $r_n = (E_n + \frac{B^2}{r_n^2}) = h;$ 

which implies

$$r_n = r_{n;0}$$
 and  $r_n = \frac{1}{h} E_n + \frac{B^2}{r_{n;0}^2} t + r_{n;0}$ : (16)

In consequence, the resulting K as in (15) will typically not correspond to the critical points of the functional given in (3). However, in such a case the  $a_n$ 's will oscillate each with a di erent frequency, which we may interpret as an uncorrelated evolution of the corresponding components (or electrons). W hen all  $a_n$ 's are in sync at all times, and oscillate with the frequency, say, then (16) shows that necessarily

 $r_n = \frac{B}{(E_{r_n})^{1-2}}$ 

and so we are again in the regime (7), and so K is a critical point of the functional . This is a complem entary phenom enon to that of phase correlation, which has been discussed in the previous section and illustrated in the gures. In particular, the phase-correlated regime will remain such when the evolution follows the pattern prescribed in (14).

As a digression, it is interesting to note in the context of (13) that at least in the free electron model, when the system is in a state K SK then the expected value of the single-particle H am iltonian is

$$hH i = trace(H K S K) = (4);$$

where the (4) depends on the energy gap 4 at the Ferm i level, although it is not equal to it, and ! 0 when 4 ! 0. This is veried by a direct calculation via the continuous approximation in the momentum space.

It is also interesting to observe that in principle the h in (14) could represent a Herm itian matrix (of the same dimension as K). However, I do not see any application for this latter fact at present.

# 4 Constraints, extensions and veri ability

A question arises as to whether there m ay be external physical constraints on the unitary part U of the transform K. The Figure demonstrates that two solutions corresponding to the same single-particle H am iltonian, yet a di erent selection of the unitary component, say U 2 U (N), will have signi cantly di erent physical properties. One would like to know how such di erent solutions can be realized in a physical system. It seems natural to expect that di erent states m ay be prepared via a cyclic perturbation of

the single-particle Ham iltonian. W hat I have in m ind here is quite sim ilar in spirit to the phenom enon of the Berry phase (cf. [1]) and what we have learned from it. In other words, one needs to consider a parameter space indexing the single-particle Ham iltonian. As one walks along a loop in the parameter space, the evolution equation (14) forces the corresponding states K to trace a path in the total space of a U (N)-principal bundle. In analogy to the Berry phase theory, the (non-Abelian !) bundle is endowed with a natural geometry, i.e. a principal connection and its curvature, which are determined by the neproperties of the perturbation of the Hamiltonian and the resulting evolution of states. A careful look at the various holonom y questions in this geometry may bring answers as to the constraints on the possible values of the non-Abelian phase and its stability. Depending on the answers, this point may have a variety of interesting implications and applications in materials engineering. A study of feasible perturbations and a construction of a suitable geometric formalism to describe such non-Abelian phase phenom ena in the context of M ecoscopic M echanics will be attempted in the future, circum stances perm itting.

As regards the problem of verifying the M eM experimentally several routes could be taken, even now. As we have pointed out already, the picture of the m agnetic vortex obtained in the M eM depends explicitly on the characteristic of the m aterial, which fact opens plethora of natural questions for experiment as well as theory. The m agnetic vortices arising in the M eM have a very de nite spectral prole, which could, at least in principle, be veri ed experimentally. M oreover, due to the particular form of the operator K, the M eM can be attuned to perturbation analysis, e.g. via the Lippm an-Schwinger type approach. Now, it seems quite realistic to try and com pare predictions of the M eM with experiment for carefully designed scattering and other perturbation experiments. The predictions we have in m ind pertain to the spectral prole of the m agnetic ux, but also its elects, e.g. on the electrons at the Ferm i level.

Finally, I would like to brie y signal that the entire fram ework of the M esoscopic M echanics adm its a natural generalization to the noncommutative setting that would incorporate the electron spin into the picture. To let on the crux of the matter, replacing the phase factors in formula (7) by a collection of unitary, say, 2-by-2 matrices still yields a solution of the Euler-Lagrange equation (4). This leads to some immensely interesting questions. Separately, just as the original formulation of the M eM presented here parallels the Schrodinger mechanics, the theory also admits a relativistic formulation in parallel to the K lein-G ordon type setting. It is important to ask if there is also a D irac type relativistic formulation. I have no complete answers to all these questions at present.

# 5 The role of the NMT

There are a few reasons to evoke here some highlights of the (fully) Nonlinear M axwell Theory. First, as already explained the NMT leads to the M esoscopic M echanics, and in a way the latter is deduced from the form er. Secondly, it is worthwhile to realize that the M eM is part of a broader fram ework that has already been shown to provide a phenom enological m odel of som e landm ark low-tem perature phenom ena:

```
m agnetic vortex lattice (cf. [7])
m agnetic oscillations (cf. [5])
charge stripes (cf. [8])
superconductivity (cf. [8])
```

Yet another reason is to announce that the NMT has been tied to the fundam ental principles via the M esoscopic M echanics.

The Nonlinear M axwell Equations couple the electric and the m agnetic elds (resp. E and B) to a scalar real-valued eld variable f. In a certain sense f is dual to the dynam ic variable K of the M esoscopic M echanics. W hen we are allowed to assume that the electric and m agnetic eld vectors are not perpendicular

$$\vec{E} \quad \vec{B} \in 0;$$
 (17)

the N on linear M axwell E quations can be rew ritten in an especially interesting form :

$$\frac{\partial \mathbf{E}}{\partial t} + \mathbf{r} \quad \mathbf{E} = 0 \tag{18}$$

$$\mathbf{r} \quad \mathbf{B} = \mathbf{0} \tag{19}$$

$$\left(\frac{\partial E}{\partial t} + F\right) = (E B)r hf$$
(20)

$$\frac{(\underline{\theta}\underline{\mathbf{E}}')}{(\underline{\theta}\underline{\mathbf{t}})} \mathbf{r} = (\underline{\mathbf{E}}' \cdot \underline{\mathbf{B}}') \frac{\underline{\theta}}{(\underline{\theta}\underline{\mathbf{t}})} \ln \mathbf{f}$$
(21)

$$(\frac{\theta^2}{\theta t^2} + 4)f + (jBf j jEf)f = f:$$
 (22)

Note that the term  $(r \in B)$  featured in the equation (20) has the meaning of the magnetic ux modulated by (\residing on") the electric charge. This concept pervades the whole theory, including the M esoscopic M echanics. It is easily seen that in two spacial dimensions the system can be reduced to a single nonlinear scalar equation:

$$4 f(x;y) + \frac{B^{2}}{f(x;y)} = f(x;y); \qquad (23)$$

which is the Euler-Lagrange equation for the critical points of the functional

7

$$L(f) = \frac{1}{2}^{Z} jr f j^{2} + B^{2} ln(f)$$
(24)

subject to the constraint:

$$f^2 = const:$$
 (25)

The functional L is neither bounded below nor above, so that one is boking at the problem of existence of local extrem a. This functional was studied via a custom -designed asymptotically stable discrete approach in [7]. The functional (24) is the precursor of (3), where the function f is replaced with an operator K. The description of the magnetic vortex lattice given in [7] is a classical counterpart of what has been presented in Section 2.

The spotting of one of the basic features of magnetic oscillations within the framework of the NMT is a beautiful and somewhat mysterious phenomenon worthy a longer comment. As already mentioned in Section 1, condensation of electrons at the Landau levels in conjunction with the Ferm i surface crossing result in magnetic oscillations, e.g. the longitudinal resistivity in the QHE experiment undergoes quantum oscillations that are in a certain way correlated with the plateaus of Hall resistance. To obtain a quantitative picture of the oscillations (in metals) one needs to calculate the therm odynam ic potential and observe its dependence on the energy levels as the magnetic eld is switched on. This results in the so-called Lifshitz-K osevich form ula (cf. [4]). Experiment shows that the oscillating macroscopic parameter invariably displays a characteristic distorted-sinusoidal pattern. However, this fact cannot be accounted for by the Landau-Ferm ipicture itself, and neither does it follow from the said form ula, but is justiled via the ferrom agnetic feedback and so it requires the assumption of ferrom agnetism. Quite surprisingly, the same pattern occurring in much the same context is intrinsically present in the Nonlinear Maxwell Theory [5], which of course has nothing to do with the ad hoc argument from ferrom agnetism.

Finally, it needs to be emphasized that the M esoscopic M echanics is not the result of canonical quantization of the N onlinear M axwell Theory. I do not consider the latter task in this article but I think a brief sketch of w hat would be involved is appropriate for the sake of completeness. The system of equations (18)-(22) is obtained from gauge-theoretic equations:

$$dF_A = 0 \tag{26}$$

$$(\mathbf{fF}_{\mathbf{A}}) = 0 \tag{27}$$

$$2f + \mathcal{F}_{A} \mathcal{J}f = f:$$
 (28)

where A is the electrom agnetic vector potential, so that the corresponding electrom agnetic eld is  $F_A = dA$ . In particular, when the system is written in this form the assumption (17) is no longer required. It is important to realize that the equations (26)–(28) are not of the Euler-Lagrange type for any Lagrangian (cf. [8]). This may at a rst glance appear un-physical, and so deserves a more detailed comment. An interesting idea one could try and pursue is that the equations may be completed to an Euler-Lagrange system by coupling them to an additional eld, but this is not a solution I would like to put forward here. A more direct possibility is in that the equations can be deformed in a continuous (adiabatic) manner so that the resulting system will in fact correspond to the critical points of a certain Lagrangian, and additionally the deform ed system will have the same two-dimensional reduction (23). These objectives are all achieved by the following simple trick. Use an auxiliary function

$$'(x) = (c \ln j x j)^{-1}$$

for a constant c, and consider the functional

7

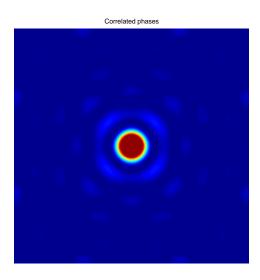

$$'(f)F_{A}J^{2} + jr_{(t,x)}fJ^{2}$$

subject to the constraint  ${}^{R}f^{2} = const.$  A direct calculation shows that the critical points of this functional satisfy a system of equations similar to (26)-(28). In fact, I predict that this new system of equations is indeed an adiabatic deform ation of the original equations, and its solutions display closely similar behavior to (26)-(28). The point is that the function f assumes values in a bounded interval in physically interesting solutions of the NM and so, for a suitable choice of the constants, f will be well approximated by ' (f). Moreover, a direct calculation shows that the deform ed system has the same two-dimensional reduction (23). That the adiabatically deform ed system can be quantized in a canonical way is a fact of signi cance.
