

Theory for Gossamer and Resonating Valence Bond Superconductivity

J. Y. Gan¹, F. C. Zhang^{2,3}, Z. B. Su¹¹Institute of Theoretical Physics, Chinese Academy of Sciences, Beijing, China²Department of Physics, The University of Hong Kong, Hong Kong³Department of Physics, University of Cincinnati, Cincinnati, Ohio 45221 [1]

We use an effective Hamiltonian for two-dimensional Hubbard model including an antiferromagnetic spin-spin coupling term to study recently proposed gossamer superconductivity. We formulate a renormalized mean field theory to approximately take into account the strong correlation effect in the partially projected Gutzwiller wavefunctions. At the half filling, there is a first order phase transition to separate a Mott insulator at large Coulomb repulsion U from a gossamer superconductor at small U . Away from the half filling, the Mott insulator is evolved into an resonating valence bond state, which is adiabatically connected to the gossamer superconductor.

1. Introduction

Since the discovery of high temperature superconductivity in the cuprates [2, 3], there have been a lot of theoretical efforts trying to understand the microscopic mechanism for it. One of the scenarios was initiated by Anderson [4], who proposed the idea of resonating valence bond (RVB) state for the observed unusual properties in these compounds. A minimum model for cuprates was argued to be 2-dimensional Hubbard or its equivalent t - J model in the large U limit [4, 5]. In the RVB picture, each lattice site is either unoccupied or singly occupied by a spin-up or spin-down electron. The spins are coupled antiferromagnetically without long range order. The charge carriers move in the spin background and condense to a superconducting state [6, 7, 8, 9, 10, 11, 12]. In this scenario, the undoped cuprate with density of one electron per site is a Mott insulator, and the superconductor is viewed as a doped Mott insulator. Many experimentally observed properties in cuprates, such as the d -wave symmetry in superconductivity [13, 14], the pseudogap phenomena [15], and the linear doping dependence of the superfluid density in the underdoped region [16], seem to be consistent with the RVB mean field theory. On the other hand, while mean field theories and variational calculations show the superconductivity in the doped Hubbard or t - J models, more direct numerical calculations on these models remain controversial and have been unable to provide unambiguous answers to this question [17, 18, 19, 20, 21, 22].

Very recently, Laughlin has proposed an interesting new notion, the gossamer superconductivity, for high T_c superconducting Cu-oxides [23]. In a gossamer superconductor, the superfluid density is tenuous, in contrast to the conventional superconductor. He proposed an explicit many body wavefunction for that state, which is a partially Gutzwiller projected BCS state (Eq. (2) below). The partial projection operator enables one to construct its inverse operator. Using these operators, Laughlin has further proposed a Hamiltonian, for which the partially projected BCS state is an exact ground state. Exact solu-

tions play important role in many physical problems. By expanding that Hamiltonian, Laughlin showed that the superconducting ground state requires a large attractive interaction in addition to a large on-site Coulomb repulsion. This raises the question if the Hubbard or t - J models capture the basic physics in cuprates.

In a previous paper, one of us argued that the effective Hamiltonian of the Hubbard model acting on the Gutzwiller's wavefunction should include a spin-spin coupling term, and the on-site Coulomb repulsion plays both the roles in projecting out (partially or completely) the double occupied state and in generating an attractive pairing interaction [24]. Although any variational calculation cannot make a conclusion about the exact ground state, it is clear that the spin-spin coupling generated from the Hubbard U should capture some basic features in cuprates including its superconductivity. Nevertheless, Laughlin's idea of gossamer superconductivity is interesting. The wavefunction he proposed enables us to study the phase transition between a Mott insulator and a gossamer superconductor at the half filled electron density and to study the strong coupling RVB state from a new viewpoint: namely its adiabatic continuation to the intermediate coupling gossamer state.

In this paper, we use an effective Hamiltonian (Eq. (1) below) for 2-dimensional Hubbard in square lattice to systematically study the partially projected Gutzwiller wavefunction. We are interested in the competition between the Mott insulator and the superconductor. Here we shall neglect the possible antiferromagnetism in the model, which will be a subject in a future publication. We use Gutzwiller's approximation to replace the strong correlation in the projection by a set of renormalized factors, and to use a renormalized mean field theory to study the ground state and the elementary excited states of the system. Our main results can be summarized below. At the half filling, the ground state is a Mott insulator at large U , and a gossamer superconductor at small U . The transition is first type in the physically interesting parameter region. The charge carrier density and the superconducting order parameter change discontinuously from zero in the Mott insulating phase to a finite

FIG. 1: Snap shots for a) A spin liquid Mott insulator; b). A RVB superconducting state; and c). A gossamer superconducting state. Each bond connects an up-spin and a down-spin and open circle represents the hole.

value at the critical value of U . Away from the half filled, the gossamer superconducting state changes continuously from its state at the half filled, while the Mott insulating phase becomes RVB superconducting. The gossamer and RVB superconducting states have the same pairing symmetry, and their superconducting order parameters are both suppressed by a unified renormalized factor, which quantitatively characterizes the smallness of the superfluid density. Therefore, the gossamer and RVB superconducting states are adiabatically connected. The gossamer superconducting state at the half filled may be viewed as a RVB state with equal number of independent empty and doubly occupied sites. These empty and doubly occupied sites provide "parking space" for singly occupied electrons to move through the lattice. From this point of view, the relative reduction of U respected to the kinetic energy, which may be realized by applying the pressure [25], plays a similar role as the chemical doping. The gossamer superconductivity may have already been realized in organic superconductors [26]. In Fig. 1, we schematically show snap shots for a Mott insulator, an RVB state, and a gossamer superconducting state.

This paper is organized as follows. In Section 2, we introduce the model and the variational wavefunction. In Section 3, we formulate a renormalized mean field theory to study the variational wavefunction. Section 4 is devoted to the phase transition between the Mott insulator and the gossamer superconductor at the half filled. Detailed discussions on the gossamer and RVB superconductivity are given in Section 5. The paper is concluded with a summary in Section 6.

2. The Model and the Variational Wavefunction

We study an effective Hubbard Hamiltonian in a square lattice,

$$\begin{aligned} H &= H_t + H_s + H_U \\ H_t &= \sum_{\langle ij \rangle} (t_{ij} c_i^\dagger c_j + \text{h.c.}) \\ H_s &= J \sum_{\langle ij \rangle} S_i \cdot S_j \end{aligned} \quad (1)$$

$$H_U = U \sum_i n_i^\uparrow n_i^\downarrow$$

In the above equations, c_i is the annihilation operator of an electron of spin \uparrow at the lattice site i , and $n_i^\uparrow = c_i^\dagger c_i$. The sum is over the nearest neighbor pairs of $\langle ij \rangle$, and $U > 0$ is the intra-site Coulomb repulsion. Without loss of generality, we consider the case $t > 0$. In this Hamiltonian, we have introduced an antiferromagnetic spin-spin coupling term to account for the effect of the virtual electron hopping process. In the large U limit, $J = 4t^2/U$. This model may be viewed as an effective Hamiltonian of the Hubbard model. The inclusion of the antiferromagnetic spin coupling appears consistent with the weak coupling renormalization group analysis [27], and is appropriate in the variational approach studied here. In the limit $U \rightarrow 1$, the model is reduced to the $t-J$ model. Very recently, a similar form of the Hamiltonian has been derived by using two subsequent canonical transformations starting from the Hubbard model at large U limit [28]. In the Hilbert space with the fixed number of the doubly occupied electron sites on the lattice, it has been shown that the Hubbard model may be mapped onto Eq. (1) with the constraint that the hopping process in H_t is limited to the corresponding Hilbert space, namely it does not change the electron double occupation. Here we shall consider Eq. (1) from a phenomenological point of view, and study its solutions within the framework of Gutzwiller's variational approach. We shall consider J to be an independent parameter.

Due to the perfect nesting and the van Hove singularity in the density of state, the ground state of Hamiltonian (1) at the half filling (electron density $n = 1$ per site) is an antiferromagnet for arbitrarily small value of U even in the absence of the spin-spin coupling term. The spin-spin coupling further enhances the magnetism. In this paper, however, we shall focus on the insulating and metallic phases of the problem, and will not include the magnetic long range order.

We study the model using a variational trial wavefunction proposed by Laughlin [23],

$$\begin{aligned} |j_{GS}\rangle &= \sum_i |j_{BCS}\rangle_i \\ &= \frac{1}{\sqrt{N}} \sum_i (1 - n_i^\uparrow n_i^\downarrow) |j_{BCS}\rangle_i \end{aligned} \quad (2)$$

with $|j_{BCS}\rangle$ a BCS-type superconducting state, given by

$$|j_{BCS}\rangle = \sum_{\mathbf{k}} (u_{\mathbf{k}} + v_{\mathbf{k}} c_{\mathbf{k}}^\dagger c_{-\mathbf{k}}^\dagger) |j\rangle \quad (4)$$

where $|j\rangle$ is the vacuum, and $u_{\mathbf{k}}$ and $v_{\mathbf{k}}$ are variational parameters, satisfying the condition

$$u_{\mathbf{k}}^2 + v_{\mathbf{k}}^2 = 1$$

is a projection operator to partially project out the doubly occupied electron states on each lattice site i .

The state $|j_{GS}\rangle$ may be considered as a generalization of the previously studied partially projected non-interacting electron state [29, 30, 31] to include the superconducting state. In the limiting case $u_k v_k = 0$, $|j_{BCS}\rangle$ is reduced to the non-interacting electron state, and

$$|j_{GS}\rangle = |j_{FL}\rangle;$$

where $|j_{FL}\rangle$ is the ground state of the non-interacting electron system, given by $|j_{FL}\rangle = \prod_k c_k^\dagger c_k |0\rangle$, with

the product running over all the k 's within the Fermi surface. $|j_{GS}\rangle$ is a natural generalization of the usual BCS state to strongly correlated systems. It connects the usual BCS state to the RVB state, characterized by the parameter δ , which takes the value between 0 and 1. $\delta = 0$ is a normal BCS state. At $\delta = 1$, the projection operator projects out all the doubly occupied electron states, and $|j_{GS}\rangle$ is reduced to the RVB state [4]. At the half filling and at $\delta = 1$, each lattice site is occupied by a single electron, and the system is a Mott insulator. Therefore, the wavefunction $|j_{GS}\rangle$ can be used to study superconductor-insulator transition.

3. The Renormalized Mean Field Theory

We now proceed the variational calculations to determine the parameters u_k, v_k . Without loss of generality, we consider the electron density $n = 1$. The variational energy per site $E = \langle H \rangle$ is given by

$$E = U d + \langle H_t \rangle + \langle H_J \rangle \quad (5)$$

where $d = \langle n_i n_{i\pm} \rangle$ is the average electron double occupation number. $\langle Q \rangle$ is the expectation value of the operator Q in the state $|j_{GS}\rangle$. For brevity, $\langle H_t \rangle, \langle H_J \rangle$ stand for their average values per site. d is a function of δ , and $0 \leq d \leq 1$. The first term in Eq. (5) is the intra-site Coulomb interaction energy, while the second and the third terms are the average kinetic and spin-spin correlation energies, respectively.

The variational calculations can be carried out using variational Monte Carlo method [8, 32, 33, 34]. Here we use the renormalized Hamiltonian approach to treat the projection operator approximately [7]. In this approach, the effect of the projection operator is taken into account by a classical statistical weighting factor, which multiplies the quantum coherent result of the non-projected state. This method (Gutzwiller method hereafter) was first proposed by Gutzwiller [30], and has been applied to study strongly correlated systems by many others [7, 29, 31]. Let $\langle Q \rangle_0$ be the expectation value of Q in the state $|j_{BCS}\rangle$, then the hopping energy and the spin-spin correlation in the state $|j_{GS}\rangle$ are related to those in the state $|j_{BCS}\rangle$ by,

$$\langle c_i^\dagger c_j \rangle = g_t \langle c_i^\dagger c_j \rangle_0$$

FIG. 2: The Gutzwiller's renormalization factors, g_t and g_s , as functions of the double occupation number d , obtained from Eqns. (6). $n = 1$.

$$\langle S_i S_j \rangle = g_s \langle S_i S_j \rangle_0 \quad (6)$$

The renormalized factors g_t and g_s are determined by the ratio of the probability of the physical processes in the states $|j_{GS}\rangle$ and $|j_{BCS}\rangle$. Following the counting method described in the literature [7], we have

$$g_t = \frac{(n-2d) \binom{p-1}{d} \binom{p-1}{n+d}}{(1-n/2)^n}$$

$$g_s = \frac{(n-2d)^2}{(1-n/2)^2 n^2} \quad (7)$$

The expression for g_t is the same as in the early literature [29]. In the limit $d = 0$, Eqns. (7) recover the previous results derived for the t - J model [7]. These renormalized factors quantitatively describe the correlation effect of the on-site repulsion. $g_t \leq 1$, and $g_t < 1$ at small d and small δ , representing the reduction of the kinetic energy due to the projection. $4 \geq g_s \geq 1$, and $g_s = 4$ at $d = 0$ and $\delta = 0$, representing the enhancement of the spin-spin correlation due to the projection. In Fig. 2, we plot g_t and g_s as functions of the double occupation number d for various electron densities.

In terms of these renormalization factors, we can define a renormalized Hamiltonian given by

$$H^0 = g_t H_t + g_s H_s + H_U \quad (8)$$

The expectation value of H in the state $|j_{GS}\rangle$ can be evaluated in terms of the expectation value of H^0 in the state $|j_{BCS}\rangle$. We obtain,

$$E = \langle H \rangle_0 = U d + g_t \langle H_t \rangle_0 + g_s \langle H_J \rangle_0 \quad (9)$$

In the renormalized Hamiltonian approach, the original variational parameters $f_k; v_k; u_k g$ are transformed into the variational parameters $f d; v_k; u_k g$. There is one to one correspondence between δ and d . Within the Gutzwiller approximation, one can analytically calculate

$d = \ln_1 n_i \# i$, and one finds [30, 31],

$$(1 - \frac{1}{d})^2 = \frac{d(1 - n + d)}{(n-2 - d)^2} \quad (10)$$

The energy in Eq. (9) is evaluated for the fixed number of electrons N_e . We introduce a Lagrangian multiplier \sim , and define

$$K = H^0 - \sim \left(\sum_i n_i - N_e \right) \quad (11)$$

We then have $E = \hbar K i_0$, being subject to the condition $\partial \hbar K i_0 / \partial \sim = 0$, or

$$2 \sum_{\mathbf{k}} v_{\mathbf{k}}^2 = n \quad (12)$$

Below we consider the case $u_{\mathbf{k}}$ and $v_{\mathbf{k}}$ to be real. Evaluating Eq. (11), we obtain (lattice constant = 1),

$$E = U d + \sim + 2 \sum_{\mathbf{k}} (g_t \cos k_x - \sim) v_{\mathbf{k}}^2 + \sum_{\mathbf{k}, \mathbf{k}^0} V_{\mathbf{k}} V_{\mathbf{k}^0} (v_{\mathbf{k}}^2 v_{\mathbf{k}^0}^2 + u_{\mathbf{k}} v_{\mathbf{k}} u_{\mathbf{k}^0} v_{\mathbf{k}^0}) \quad (13)$$

where

$$V_{\mathbf{k}} = \frac{3}{2} g_s J (\cos k_x + \cos k_y) \\ \mathbf{k} = 2t(\cos k_x + \cos k_y) \quad (14)$$

Carrying out the variational procedure with respect to $u_{\mathbf{k}}$ and $v_{\mathbf{k}}$, we obtain

$$u_{\mathbf{k}}^2 = \frac{1}{2} (1 + \mathbf{k} = E_{\mathbf{k}}) \\ v_{\mathbf{k}}^2 = \frac{1}{2} (1 - \mathbf{k} = E_{\mathbf{k}}) \quad (15)$$

where

$$E_{\mathbf{k}} = \frac{q}{\frac{2}{\mathbf{k}} + \frac{2}{\mathbf{k}}} \quad (16)$$

The variational parameters \mathbf{k} and \mathbf{k} are related to the particle-particle amplitude \mathbf{k} and the particle-hole pairing amplitudes \mathbf{k} by,

$$\mathbf{k} = x \cos k_x + y \cos k_y \\ \mathbf{k} = \tilde{\mathbf{k}} (x \cos k_x + y \cos k_y) \quad (17)$$

In the above equations, we have introduced two correlation functions in the unprojected state j_{BCSi} ,

$$= \frac{\hbar c_{i\#} c_{i+}}{P} ; \quad \mathbf{q} = c_{i+} \# i_0 \\ = \frac{\hbar c_{i+}^y c_{i+}}{1} i_0 \quad (18)$$

with $\mathbf{x} = x; y$, the unit vectors on the lattice, and

$$\tilde{\mathbf{k}} = [2qt(\cos k_x + \cos k_y) - \sim] (3g_s J = 4) \quad (19)$$

For the d-wave pairing state, which has the lowest energy within this class of states as suggested in the previous studies for the tight-j model [7, 9, 10, 36], we have $x = y = \frac{1}{2}$, and $x = y = \frac{1}{2}$. \mathbf{k} and \mathbf{k} are determined by the coupled gap equations,

$$\mathbf{k} = \sum_{\mathbf{k}} (\cos k_x) \mathbf{k} = E_{\mathbf{k}} \\ \mathbf{k} = \sum_{\mathbf{k}} (\cos k_x) \mathbf{k} = E_{\mathbf{k}} \quad (20)$$

These gap equations must be solved simultaneously with the hole concentration equation, Eq. (12), which can be rewritten as $\mathbf{k} = E_{\mathbf{k}}$, with $\mathbf{k} = 1 - n$. The variation

with respect to d leads to the equation

$$\frac{\partial E}{\partial d} = U + \frac{\partial g_t}{\partial d} \hbar H_t i_0 + \frac{\partial g_s}{\partial d} \hbar H_J i_0 = 0 \quad (21)$$

In terms of \mathbf{k} and \mathbf{k} , the energy is given by

$$E = U d - 4nqt - (3g_s J = 4) (\frac{2}{\mathbf{k}} + \frac{2}{\mathbf{k}}) \quad (22)$$

where \mathbf{k} and \mathbf{k} are the solutions of the gap equations, and both are functions of d . In the case there are multiple solutions for d from Eq. (21), the ground state is determined by the global energy minimum. Alternatively, we may solve the gap equations for given values of d , and calculate $E(d)$ to find the optimal value of d to determine the ground state and the ground state energy. The chemical potential of the system, $\mu = \partial E / \partial n$, is given by

$$\mu = \sim + \frac{\partial g_t}{\partial n} \hbar H_t i_0 + \frac{\partial g_s}{\partial n} \hbar H_J i_0 \quad (23)$$

Note that chemical potential here is different from the Lagrangian multiplier \sim in the renormalized mean-field theory. This is because the renormalized factors g_t, g_s to be also functions of electron density n .

4. Mott Insulator-Gossamer Superconductor Transition

In this section, we discuss the variational solutions at the half-filled case. At the half-filling, the trial wavefunction j_{GSI} describes either a Mott insulator if $\mathbf{k} = 1$ (i.e. $d = 0$), or a superconducting state if $\mathbf{k} < 1$ (i.e. $d > 0$). If \mathbf{k} is close to 1, or d is very close to zero, j_{GSI} describes a gossamer superconducting state.

We expect a Mott insulator at large U and a superconducting state at small U . This can be examined qualitatively without carrying out the quantitative calculations. At the half-filling, $q = 8(1 - 2d)d$, and $g_s = 4(1 - 2d)^2$. Eq. (21) becomes

$$U + 8(1 - 4d)\hbar H_t i_0 - 16(1 - 2d)\hbar H_J i_0 = 0 \quad (24)$$

Since both $\hbar H_{\uparrow i_0}$ and $\hbar H_{\downarrow i_0}$ are finite, there will be no solution of Eq. (24) if U is sufficiently large. This indicates that the ground state corresponds either $d = 0$ or $d = d_{\max}$, the allowed maximum value of d . The repulsive nature of U excludes the latter, and it follows that the Mott insulating state with $d = 0$ is the ground state. We believe that the qualitative result for the existence of the Mott insulating phase at large but finite U is robust. Note that in the Gutzwiller's wavefunction, the doubly occupied site and the empty site are not correlated. At the half filling, d represents the carrier density n and is proportional to the Drude weight in the a.c. conductivity, $n e^2 \tau / m$, with m the effective mass. We remark that the parameter d in our Gutzwiller approach is different from the usual double occupation number \bar{d} (for example, the double occupation calculated in the exact diagonalization of a finite size system). In the latter case, \bar{d} also includes the contribution from the virtual hopping process. Therefore, the double occupied site is bound to the empty site, and the double occupation number \bar{d} does not represent the mobile carriers.

In the insulating phase, the ground state is the same as that of the Heisenberg model. Within our theory, the ground state energy is given by

$$E_0 = -3J \left(\frac{2}{3} + \frac{2}{3} \right) \quad (25)$$

with

$$\begin{aligned} \frac{1}{3} &= \frac{1}{3} = C = \frac{P}{2} \\ &= \frac{1}{8} \sum_{\mathbf{k}} \frac{1}{\cos^2 k_x + \cos^2 k_y} = 0.339: \quad (26) \end{aligned}$$

At small U , one expects a metallic ground state, except in the special cases due to the band effect, such as having the Von Hove singularity and perfect nesting in H_{\uparrow} . In this paper, we will not consider the special band effect. Therefore, we expect a metal-insulator transition at a finite $U = U_c$ in the general case, with the metallic phase to be superconducting provided that $u_{\mathbf{k}} v_{\mathbf{k}} \neq 0$. This is the Mott insulator-gossamer superconductor transition.

We now discuss the phase transition in details. We solve the gap equations for the fixed d and determine the transition point U_c and the nature of the transition. The phase diagram in the parameter space U and J/t is plotted in Fig. 3. The critical U_c separates the Mott insulating phase from the gossamer superconducting phase. We can choose the mobile carrier density as the order parameter, which is proportional to d . The phase transition is classified as the second type if $d \neq 0$ and the first type if $d \neq d_c > 0$ as $U \rightarrow U_c$ within the metallic phase. This classification is consistent with the usual zero temperature quantum phase transition, where the nature of the phase transition depends on the continuity or discontinuity of the order parameter. We find the transition to be the first order at $0 < J/t < \infty$, and the second order

FIG. 3: Phase diagram at the half filling.

at $\infty < J/t$, with $\infty = 2$. At $J = 0$, the present theory is reduced to the Brinkman-Rice theory for metal-insulator transition [29] for the projected non-interacting electron state. In that case, we find $U_c/t = 12.8$. From Fig. 3, we see that $U_c(J \neq 0) = U_c(J = 0)$, so that the critical value of U is continuous at $J = 0$. However, the transition is the second type at $J = 0$, while it is the first type for any small but finite J/t .

Let us first discuss the first order phase transition in the region $0 < J/t < 2$. In Fig. 4, we show the energy E as a function of d for several values of U at a typical parameter $J/t = 1/3$. E is not a monotonic function of d for U near U_c . As d increases from $d = 0$, E first increases linearly, then decreases, then increases again. There is a local energy minimum around $d = 0.02$, which develops and becomes a global minimum as U approaches U_c from the insulator side. The local minimum $E(d_c)$ at $d = d_c$ represents a metallic solution, and $E(d = 0)$ represents an insulator solution. The critical value for the Mott insulator and gossamer superconductor transition is determined by the condition $E(d_c) = E(d = 0)$. From Fig. 4, we have $U_c/t = 10.23$ for $J/t = 1/3$. At $U > U_c$, $d = 0$, and the ground state is an insulator. At $U < U_c$, $d \neq 0.02$, and the ground state is a gossamer superconducting state. In Fig. 5, we plot d as a function of U . d is approximately linear in U till the transition point U_c . The discontinuity in d is about 0.02. We conclude that the Mott insulator-gossamer superconductor phase transition in this most relevant region is first type. The carrier density is discontinuous at the phase transition point. Since d is proportional to the carrier density, this type of first order transition should be observable in the electric transport or in the a.c. conductivity measurements.

For large ratio of J/t , our calculations show that the phase transition is second order. This is illustrated in Fig. 6 for E v.s. d in the case of $J/t = 3$. The transition occurs at $U_c = 2.58t$, and d changes continuously across U_c .

A special case is $J = 0$. In this limit, $j_{GSi} = j_{FLi}$, and our theory is reduced to the previous one for the projected Fermi liquid state. The energy in Eq.

FIG. 4: The energy E as a function of d for U around the critical value U_c at $\delta = 0$. The ratio $J=t = 1=3$.

FIG. 5: The double occupation number d as a function of U at $\delta = 0$ and $J=t = 1/3$.

(9) at the half filling becomes

$$E = U d - \frac{1}{2} \sum_{\mathbf{k}} \epsilon_{\mathbf{k}}^2 \cos k_x + \cos k_y$$

$$= U d - 128 d (1 - 2d) t^2 \quad (27)$$

From this we find $U_c/t = 128 = 2^{13}$. d is continuous at U_c so that the transition is second type.

Our result on the first order phase transition in the physically interesting region (small but non-zero $J=t$) is somewhat unexpected. We argue that the first order

FIG. 6: The energy E as a function of the double occupation number d for several values of U around the critical value U_c with $\delta = 0$ and $J=t = 3$.

transition between the Mott insulator and the gossamer superconductor is due to the interplay of the kinetic and spin-spin correlation energies. This interplay was not included in the previous study of the Gutzwiller approach but is taken into account here. To illustrate the effect of the interplay to the nature of the phase transition, we consider the limiting case $0 < J=t < 1$, and expand the energy E of Eq. (22) at $n = 1$ for small d ,

$$E(d) = E_0 + (U - U_{c0})d + \frac{1}{2}d^2 + O(d^3) \quad (28)$$

where E_0 is the energy at $d = 0$ given by Eq. (25), $U_{c0} = 16 \frac{J}{t} \frac{C}{2} t - 12 C^2 J$ is the solution of $\partial E / \partial d = 0$ at $d = 0$, given by Eq. (24). $\epsilon_{\mathbf{k}} = [32 (\partial \epsilon / \partial d)_{\mathbf{k}=0} - 32 \frac{J}{t} C] t$. The J -dependence in $\epsilon_{\mathbf{k}}$ has been neglected since $J=t < 1$. Note that the kinetic energy is proportional to $\epsilon_{\mathbf{k}}^2$. As d increases from 0, $\epsilon_{\mathbf{k}}$ tends to increase from $\epsilon_0 = C/2$ to gain more kinetic energy. Therefore, $\partial E / \partial d > 0$. In the limit $J=t < 1$, we have $\partial E / \partial d = (\epsilon_0)^2 d / t = J > 1$, hence the first term in the expression for $\partial E / \partial d$ dominates and $\partial E / \partial d > 0$. This demonstrates that $d = 0$ is a local maximum in energy at $U = U_{c0}$, and the phase transition occurs at a large value of U corresponding to $d > 0$ as numerically shown in Fig. 4, hence it is a first order transition. Numerically, we find that $\epsilon_0 = 34.8472$, for $J=t = 1=3$.

It is interesting to compare the gossamer superconductor-Mott insulator transition with the metal-insulator transition studied in previous literature [29]. In the Brinkman-Rice theory, the transition is second order. In that theory, the system approaches the insulating phase, the effective mass $m^* \rightarrow \infty$. In the gossamer superconductor-Mott insulator transition with small ratio of $J=t$, the insulating phase is not characterized by the divergence of the effective mass. We estimate the ratio of the effective mass to the band mass ($1/t$) at the metallic side of transition point to be $1 = g_{\mathbf{k}} = 1/(8d) \approx 6$.

The first order phase transition between metal and insulator was first pointed out by Peierls [37] and by Landau and Zeldovich [38], and examined in more great detail by Mott [39]. In their theory, an electron is always bound to a positive charge due to the long range Coulomb attraction, and the transition of a metal to an insulator at zero or very low temperatures occurs at a finite critical electron density, and must be first type. It is interesting to note that the on-site repulsion also leads to the first order transition between a specific type of metal (superconductor) and an insulator studied in the present paper, where the long range Coulomb force is not included. We also note that Florencio and Chao [40] investigated the metal-insulator transition of the Hubbard model using Gutzwiller's wavefunction by including antiferromagnetism and found the transition to be first type.

FIG. 7: The double occupation number d as a function of δ at the ratio $J/t = 1/3$ for several U 's.

5. Gossamer and RVB superconductivity

In this section, we discuss the superconducting state at the half filled as well as away from the half filled. Note that at $\delta > 0$, j_{GS} always describes a metallic state. To make the terminology clearly, we shall call the superconducting state at $U < U_c$ to be the gossamer superconductor [23, 24], and the doped Mott insulator ($U > U_c$ and $\delta > 0$) to be the RVB state [4].

We begin with the discussion of the double occupation number d as a function of the hole concentration. We solve the gap equations and find the optimal value of d . The results are plotted in Fig. 7. We find that d is always non-zero at $\delta > 0$, even in the region $U > U_c$. This suggests that the doped Mott insulator is described by a partially projected state ($\rho < 1$ in Eq. (2)). Nevertheless, d is very small for $U > U_c$. As we can see from Fig. 7, d varies from 0 to 0.01 for $U/t = 15$, which corresponds to $U = U_c \pm 1.5$. The non-zero value of d at $\delta > 0$ may be understood from the variational equation (21), which determines d . At $\delta > 0$, $\partial g / \partial d_{j=0} \neq 1$. Therefore, $d = 0$ cannot be a solution of the equation, and d must be finite. It remains to be seen if this result is due to the Gutzwiller's approximation used in our calculation. It will be interesting to further examine this issue using other methods such as the variational Monte Carlo method.

From Fig. 7, we also see that as δ increases from 0, d increases for large U while d decreases for small U . The latter may be understood as follows. In the small U case, the correlation becomes less important, and the qualitative feature between d and δ becomes similar to the uncorrelated state. For the uncorrelated Fermi liquid state, $d = (1 - \zeta)/4$, so that d monotonically decreases as δ increases.

While d is a smooth function of δ for most values of U in our study, there is a narrow region in U above U_c , d changes discontinuously at a very small δ . In Fig. 8, we show the energy E v.s. d for $U = 10.235t$, slightly above $U_c = 10.23t$, for four values of δ . At $\delta = 0$, $d = 0$

FIG. 8: Energy E as a function of d for $U = 10.235t > U_c$ at the ratio $J/t = 1/3$, for several values of δ .

corresponds to the global energy minimum, while there is a local minimum around $d = 0.02$. As δ gradually increases, the positions of the two minima change smoothly and their corresponding energies reverse their order. In this region, the optimal value of d jumps. This region is found very narrow: $10.23t < U < 10.235t$, however.

We now discuss the superconducting order parameter. The superconducting order parameter of the state j_{GS} is defined by, for the d -wave pairing,

$$\Delta_{sc}(\mathbf{r}) = \langle \mathbf{r} | \mathbf{r}' \rangle = \langle \mathbf{r} | \mathbf{r}' \rangle \quad (29)$$

and $\Delta_{sc} = \Delta_{sc}(\mathbf{x}) = \Delta_{sc}(\mathbf{y})$. We shall adopt the Gutzwiller approximation to calculate this quantity. In analogy to the derivation for the hopping energy in Eq.(6), we find that [7]

$$\langle C_{i\uparrow} C_{i+\uparrow} \rangle = g_t \langle C_{i\uparrow} C_{i+\uparrow} \rangle_0 \quad (30)$$

Therefore the order parameter Δ_{sc} is related to the variational parameter g_t in the gap equations by

$$\Delta_{sc} = g_t \quad (31)$$

In Fig. 9, we show our results for Δ_{sc} and g_t as functions of δ for three values of U : well above U_c , at U_c , and well below U_c . Note that at $U = 15t \gg U_c$, $\Delta_{sc} = 0$ at $\delta = 0$, although g_t takes a maximum. This is consistent with the Mott insulating ground state. At δ increases, the kinetic energy plays more important role in comparison with the spin-spin correlation energy, and Δ_{sc} decreases monotonically. However, Δ_{sc} shows a non-monotonic dome shape, and it first increases to reach a peak before it drops for larger U . Also note that at U_c the Mott

FIG. 9: Variational parameter Δ and superconducting order parameter Δ_{sc} as functions of the hole concentration δ for three values of U at ratio $J=t=1/3$.

insulator and gossamer superconducting state are degenerate at $\delta = 0$, and the gossamer superconducting phase continuously evolves into the metallic phase at $\delta > 0$. Shown in the figure for $U = 10.23t$ U_c is the metallic phase. The non-zero value of Δ_{sc} at $\delta = 0$ indicates the transition to be the first order.

In Fig. 10, we show Δ_{sc} and Δ as a function of U for $\delta = 0$. From this figure we can see that for $U < U_c$, Δ_{sc} and Δ both increase with U . At $U = U_c$, Δ takes a maximum while $\Delta_{sc} = 0$. Note that at small values of U , the effective Hamiltonian does not represent the original Hubbard model, and one should be cautious to interpret the results at small U .

It is interesting to point out that the superconducting order parameter Δ_{sc} in both the gossamer and RVB superconducting states are characterized by the variational parameter Δ and a small renormalized factor g_t . They have the same pairing symmetry, and the two states are adiabatically connected to each other. From this point of view, the gossamer and RVB superconductors are the same. In Fig. 11, we present a schematic diagram for the Mott insulator, gossamer and RVB superconducting states. In the parameter space of Coulomb repulsion U and of the hole concentration δ , there is a line at $\delta = 0$ and at $U > U_c$ for the Mott insulating phase. In the region $U > U_c$ and $\delta > 0$, it is the RVB superconducting phase as Anderson proposed [4]. In the region $U < U_c$, it is the gossamer superconducting phase in which both the half-filled and non-half-filled states are superconducting.

While the gossamer and RVB superconducting states are essentially the same, the chemical potential in the gossamer superconducting state is continuous at $\delta = 0$

FIG. 10: Variational parameter Δ and superconducting order parameter Δ_{sc} as functions of U at $\delta = 0$ and $J=t=1/3$.

FIG. 11: Schematic phase diagram for the Hamiltonian in parameter space U and δ .

because of the metallic phase, while Δ is discontinuous at $\delta = 0$ because the state at $\delta = 0$ is an insulator and the state at any small but finite δ is a metal within the present theory.

Below we shall study Δ quantitatively. At $\delta = 0$, $\Delta = U/2$ by electron-hole symmetry. At other value of δ , we calculate Δ using Eq. (23) after solving the gap equations. In Fig. 12, we show Δ as a function of δ . As we can see from the figure, $\Delta = U/2$ at $\delta = 0$, and is continuous for $U < U_c = 10.23t$. There is a discontinuity in Δ for $U > U_c$ at $\delta = 0$. At $U > U_c$, the chemical potential is shifted from $U/2$ at the half-filled to the lower Hubbard band away from the half-filled. To see this more explicitly, we define $\mu = (\epsilon_F - \epsilon_0)/t$ ($\epsilon_F = 0$) as a function of U is plotted in Fig. 13. As U decreases, μ decreases monotonically and reaches a finite value at $U = U_c + 0^+$,

FIG. 12: The chemical potential as a function of the hole concentration for several values of intra-site Coulomb repulsion U with $J=t=1/3$.

FIG. 13: The discontinuity in the chemical potential as a function of intra-site Coulomb repulsion U for $J=t=1/3$.

then drops to zero at $U = U_c$. The discontinuity of μ at U_c is related to the first order phase transition.

Finally, we briefly discuss the excited states. In the context of the Gutzwiller trial wavefunction, the excited states were discussed by Zhang et al. [7] for the RVB state, and recently by Laughlin for a gossamer superconductor Hamiltonian [23]. Following Zhang et al., the quasiparticle states can be defined by

$$|j_p\rangle = \sum_{k \in p} \frac{1}{\sqrt{N}} (u_k + v_k c_{k\uparrow}^\dagger c_{k\downarrow}^\dagger) |j\rangle \quad (32)$$

The quasiparticle energy E_p is defined to be the difference of the expectation values of K in Eq. (32) in this state and in the ground state $|j_{GS}\rangle$. We use the Gutzwiller method to calculate the energy and obtain [7]

$$E_p = (3g_s J = 4) \frac{q}{p} \left(\frac{1}{p} + \frac{1}{p} \right) \quad (33)$$

At the vectors p satisfying $p = 0$ (Eq. (17)), we have $E_p = j \cos k_x - \cos k_y$. Therefore, the quasiparticle energy is proportional to the parameter j , and not renormalized by the factor g_t , which is very different from the superconducting order parameter. From Fig. 9, our theory predicts the quasiparticle energy to be maximum at $\delta = 0$, and decreases as doping increases. This

feature was first found for the large- U limit Hubbard model [7], and is consistent with the "high energy pseudogap" seen in the angular resolved photoemission experiments and the experimentally observed superconducting energy gap [41, 42, 43]. Here we show that this feature appears also in the gossamer superconductor.

6. Summary

We have used the Gutzwiller variational method to study an effective Hamiltonian for 2-dimension Hubbard model. Based on Gutzwiller approximation, we have discussed the case both at the half filled and away from the half filled. At the half filled, there is a first order phase transition to separate a Mott insulator at large Coulomb repulsion U from a gossamer superconductor at small U . This is very interesting. It suggests that the on-site Coulomb repulsion can lead to the first transition between a specific type of metal and an insulator. The double occupation number d which is proportional to the carrier density changes discontinuously from zero in the Mott insulator phase to a finite value at the phase transition point ($U = U_c$). So we expect that this type of first order transition should be observable in the electric transport or in the a.c. conductivity measurements. Away from the half filled, the Gutzwiller variational state is always metallic. The gossamer superconducting state changes continuously from its state at the half filled, while the Mott insulating phase becomes RVB superconducting. The gossamer superconductor is similar to the RVB superconducting states with the same pairing symmetry, and showing the pseudogap. Their major difference is on the position of their chemical potential. The Gutzwiller method we used in this paper has previously been tested in good agreement with variational Monte Carlo method [7, 8]. We believe that the qualitative conclusions obtained here should be reliable, and refined numerical calculations such as variational Monte Carlo calculations will be interesting to examine the problem.

There are other questions that require further investigation such as the effect of the antiferromagnetism which is most plausible in this model.

We wish to thank R. Laughlin, T. M. Rice, P. W. Anderson, Y. Yamashita, and Y. Yu for many interesting discussions. This work was partially supported by the US NSF grant 0113574, and by Chinese Academy of Sciences.
