A bstract: The probability distribution of percolation thresholds in nite lattioes were rst believed to follow a norm al Gaussian behaviour. W ith increasing com puter power and $m$ ore e cient sim ulational techniques, this belief tumed to a stretched exponential behaviour, instead. H ere, based on a further im provem ent of $M$ onte $C$ arlo data, we show evidences that this question is not yet answ ered at all.

In reference $\dagger \underline{i} \mathrm{i}]$, the percolation on a N -site square lattice is treated w ith high num erical accuracy. Indeed, the best know n estim ate for the critical threshold, $p_{c}=0: 59274621(13)$, com es from this work. In order to study this kind of problem S , the authors follow a very fruitfulM onte C arlo approach which allows one to obtain continuous fiunctions of $p$, the concentration of occupied sites, nam ely the canonical-like average

$$
\begin{equation*}
R(p)={ }_{n}^{x} C_{N}^{n} p^{n}(1 \quad p)^{N}{ }^{n} R_{n} ; \tag{1}
\end{equation*}
$$

of som e quantity $R$. Here, $R_{n}$ is a uniform average over all con gurations w ith just $n$ occupied sites, i.e. a microcanonical-like average. $\mathrm{C}_{\mathrm{N}}^{\mathrm{n}}$ are sim ple binom ial factors. By lling the initially em pty lattioe, site by site at random, and repeating this process $m$ any tim es, one is able to get the discrete set of $m$ icrocanonical averages $R_{n}$ accum ulated into an $n$-histogram, over the entire

Figure 1: Spanning probability function for a xed lattioe size L (solid line). For larger and larger sizes (dotted lines), this function approaches a step. By xing som evalue $r$ at the verticalaxis, one can nd a sequence ofvalues $p_{I}$ (r) at the horizontal axis approaching the critical threshold $p_{c}$, for increasing lattice sizes.
range, $n=0,1,2::: N$. From this set of num bers, the determ ination of the continuous $p$-function $R(p)$ is straightforw ard.

In particular the authors of $\left[\begin{array}{ll}{[1]} \\ ]\end{array} \mathrm{x}\right.$ attention at the horizontal w rapping probability $R_{\mathrm{I}}(\mathrm{p})$ around a L L tonus, i.e. a square lattice w th periodic boundary conditions on both directions. In the them odynam ic lim it, this function approaches a step: $R_{1}(p)=0$ below the critical threshold $p_{c}$, and $R_{1}(p)=1$ above $p_{c}$. For nite sizes, $R_{L}(p)$ presents a sigm oid aspect sim ilar to gure 1. A good approach to $p_{c}$ is to choose some xed value $r$, and solve the equation $R_{L}(p)=r$, getting the root $p$ show $n$ at the horizontal axis. Here, one can appreciate the advantage of know ing $R_{L}$ (p) as a continuous function ofp. $K$ eeping the sam evalue $r$ and repeating thistask for a series of increasing lattice sizes (dotted lines), one gets a series of roots $\mathrm{p}_{\mathrm{L}_{1}}(r), \mathrm{p}_{\mathrm{L}_{2}}(r)$, $\mathrm{p}_{\mathrm{L}_{3}}(\mathrm{r}):::$ which converges to the desired threshold $\mathrm{p}_{\mathrm{c}}$ in the therm odynam ic lim it.

The above reasoning is valid no $m$ atter which is the xed value for $r$ one chooses. However, for the very particular choice $r=0: 521058290$, a universal probability exactly known through conform al invariance argu-
$m$ ents $\stackrel{\downarrow}{2}]$, the convergence becom es fast, i.e. the root $p(L)$ di ers from $p_{c}$ as $L^{21=}=L^{2: 75}$, where $=4=3$ is the correlation length critical exponent. The above quoted accurate value for $p_{c}$ was obtained in this way. For details, see $\left[\begin{array}{ll}{[1]}\end{array}\right]$ and references therein.

R eference [3, proposes the $m$ athem atical form

$$
\begin{equation*}
\mathrm{p}_{\mathrm{L}}(\mathrm{r})=\mathrm{p}_{\mathrm{C}}+{\frac{1}{\mathrm{~L}^{1=}}}^{\mathrm{h}} \mathrm{~A}_{0}(\mathrm{r})+\frac{\mathrm{A}_{1}(\mathrm{r})}{\mathrm{L}}+\frac{\mathrm{A}_{2}(\mathrm{r})}{\mathrm{L}^{2}}+:::^{i} ; \tag{2}
\end{equation*}
$$

for estim ators $p_{L}$ obtained from quantities like $R(p)$. The option for the w rapping probabilities around the torus and the convenient choice ofP inson's number $r=r$ lead to vanishing values for the two rst term $s A_{0}(r)=$ $A_{1}(r)=0, a \operatorname{lucky}$ coincidence which accelerates very $m$ uch the convergence.
$T$ he quantity $R_{L}(p)$ is obtained, as quoted before, by lling up the intitially em pty lattice site by site, at random. C husters of neighbouring occupied sites grow. A s soon as the horizontal w rapping along the torus is set, one books the corresponding value of $n$, the num ber of occupied sites so far, and stops the process. For that partioular sam ple, the wrapping probability $R_{L}$ is a step function, i.e. $\mathrm{R}_{\mathrm{L}}=0$ below n and $\mathrm{R}_{\mathrm{L}}=1$ above. The same routine is repeated $m$ any tim es, in order to have a probability distribution for $n$. $T$ he various step functions are then superim posed to get the $m$ icrocanonical averages $R_{n}$ in equation (1), stored in an n-histogram. F inally, the continuous canonical average $R_{L}(p)$ can be calculated for any value of $p$.

Each process of lling-up the lattioe (one sam ple) yields a single value $n$ for the statistics, i.e. just one $m$ ore entry on the $n$-histogram. In [3̄], we decided to im prove this point, by changing the de nition from wrapping to spanning probability, gure 1. We x two parallel horizontal lines on the $L \quad L$ tonus, separated by a distance of $L=2$, for instance lines $i=1$ and $i=1+\mathrm{L}=2$. The $m$ easured quantity is now the probability of having these tw o lines connected by the sam e chuster of neighbouring occupied sites, instead of the wrapping probability along the whole torus. The advantage is that we can $m$ easure the sam e thing for lines $i=2$ and $i=2+L=2$, also for lines $i=3$ and $i=3+\mathrm{L}=2$, and so on. M oreover, also vertical parallel lines can be included into this counting. At the end, from a single sam ple we store $L$ new entries into our $n$-histogram, instead of just one $m$ ore entry. $N$ ote that this advantage even increases for larger and larger lattioes.

W ithin the sam e com putational e ort, our approach allows the test of larger lattioes. Because of that, we were able to con $m$ the validity of equation (2) w ith high precision, by sam pling 27 di erent lattice sizes from
$\mathrm{L}=18$ up to $\mathrm{L}=1594$, a 8-thousand factor in number of sites. On the other hand, our de nition does not allow the chance of vanishing both $A_{0}(r)$ and $A_{1}(r)$ at once. $W$ e can have only $A_{0}(\hat{r})=0$, for a particular universal probability $\hat{\mathrm{r}}=0: 984786$ (11) num erically determ ined within the sam e w ork
 argum ents, however, in looking for con gurations which link two parallel lines, he was foroed to disregard con gurations which also wrap along the other direction. A s a result of using larger lattices but a slow er convergence rate of $L^{11}=\quad=L^{1: 75}$, we get the same gure $p_{c}=0: 59274621$ (33) 滒] as in $[\underline{1}[1]$, but w thin a 3 tim es larger error bar.

Figure 2: Test of equations (3) or (4), for tails on the left of gure 1. The ve continuous curves correspond to $L=1594,1354,1126,958$ and 802, from left to right. In each case we sam pled 4 m illion lattioe- lling processes, which corresponds to $6,5,5,4$, and $310^{9}$ entries in each $n$-histogram, respectively. The statistics is im proved by a factor over than 1000, com pared w ith [ī] for equivalent lattice sizes. The dashed lines show the altemative slopes 2 (right) or 4/3 (left). In the authors' opinion, no de nitive conclusion is possible.

The non-G aussian behaviour of the nite-lattioe-threshold distribution near the in nite-lattice criticalpoint is already stablished ${\underset{W}{1}}_{1}^{1}$. Here, we pro $t$ from the sam e sim ulationaldata in order to investigate the distribution tails, far from the critical point. W hidh is the $m$ athem atical form of the tail

Figure 3: A ltemative test of equations (3) or (4), for the sam e lattige sizes $L=1594,1354,1126,958$ and 802 , from left to right.
observed in gure 1, below the root p? O ne possible answer is a sim ple G aussian form 恔, '

$$
R_{L}(\mathrm{p}) \quad \exp \left[\begin{array}{ll}
\mathrm{K}(\mathrm{p} & \left.\mathrm{p}_{\mathrm{C}}\right)^{2} \tag{3}
\end{array}\right]:
$$

$$
\left.R_{L}(p)=\exp \left[\begin{array}{ll}
C\left(p_{C}\right. & p \tag{4}
\end{array}\right)\right] ;
$$

where the strict equality (for large $L$ and far from $p_{c}$ ) is a consequence of the periodic boundary condition [ī1], whidh holds for our data. P ro ting from this
strict equality, one can test equation (4) by constructing a plot of $\ln [\ln (R)]$ against $\ln \left(p_{c} \quad p\right)$. This was done in $\left.{ }_{[1]}^{1}\right]$, and we repeat the sam $e$ for our data, in gure 2. N ote that our range for $\ln \left(p_{c} \quad p\right.$ ) (up to 3:4 for L $10^{3}$ ) is larger than in reference [ī1] (up to $4: 6$ for the sam e size). This $m$ eans that we are testing $m$ ore deeply the distribution tails, thanks to our tridk of sam pling $L$ new entries for each run. Even $s o$, the conclusion in favour of either equation (3) or (4) is by no $m$ eans obvious. N ote a further di culty in what concems equation (3), because the leading $m$ ultiplicative constant in front of the exponential is not necessarily 1 .

A nother, perhaps better way to address the sam e question is by plotting $\ln (R)$ tw ice, against $\left(p \quad p_{c}\right)^{2}$ and $\left(p_{c} \quad p\right)^{4=3}$. Figure 3 show $s$ the result for our data. $N$ ote that our range for $\ln (\mathbb{R}$ ) (down to 16) doubles the one presented in [1i1]. The would-be G aussian case (up) presents clear positive curvatures, whereas the would -be stretched exponential (down) presents negative curvatures although not so pronounced. The exponent $4=3$ seem s to t better, but one cannot extract a clear conclusion from these data.

Stillm ore unde ned is the siluation of the other tails on the right of gure 1 , above $p_{c}$. In this case (not shown), our accuracy lim it for $\ln (1 \quad R)$ (dow $n$ to 16) is reached $m$ uch closer to $p_{c}$ than the case show $n$ in gures 2 and 3, below $\mathrm{p}_{\mathrm{c}}$.

C oncluding, we present new M onte C arlo data conceming the distribution probability of percolation thresholds on a nite square lattioe. W e address the question of the $m$ athem atical form of the distribution tails, equation (3) against (4). Even considering that our statistics is over than 1000 tim es larger than previous works, no de nitive conclusion can be extracted from our data, in what concems the asym ptotic tail exponent.
