Comment on  $\M$  icroscopic theory of network glasses"

In a recent Letter Hall and Wolynes[1] (HW) ask whether a microscopic theory of network glasses can be developed starting from a model of dense spherical uids. To do so they constrain the num ber of nearest neighbors and count their central force interactions separately. They obtain the dynam ical transition tem perature T<sub>A</sub> (below which the system is nonergodic and the motion is landscape-determ ined), and the entropy crisis (K auzm an) temperature  $T_{K}$  as functions of  $n_{b}$ , the average num ber of nearest neighbor bonds/atom . A Lindem ann melting criterion on the amplitude of nearest neighbor vibrations de nes the glass transition temperature  $T_G$ . The model shows that  $T_A = T_G$  and  $T_K = T_G$  monotonically increase and decrease, respectively, as functions of n<sub>b</sub>. For  $n_b = 2:4$ ,  $T_A = T_G = 100$ , an unreasonable result. Mode coupling theory (MCT) de nes a critical nonergodicity tem perature T<sub>c</sub> beyond which a radical change in the long time lim it of e.g. the density-density correlation function occurs. T<sub>c</sub> has been plausibly estimated for vitreous silica in m olecular dynam ics sim ulations [2] as  $T_c=T_G = 2$ . Even this tem perature is presently outside the reach of experim ental investigations [2].

How do these results compare with experiments ? There are standard procedures for extrapolating speci c heats to obtain  $T_K$ , but identifying the onset of nonergodicity at T<sub>A</sub> (or T<sub>c</sub>) is much more di cult. Chalcogenide glasses are ideal test system s because one can synthesize them over a wide range of n<sub>b</sub> by chemical alloying group IV additives in Se base glass. Fortunately, glass transitions of these systems have been recently reinvestigated [3] using m odulated DSC (MDSC), a new m ethod w hich permits separating the usual DSC heat ow endotherm  $H_{T}$  into a reversing part  $H_{rev}$  which is ergodic (and which follows the modulated T-pro le) from the nonreversing part H<sub>nr</sub> which is non-ergodic (arising from underlying tem perature dependent activated processes) as illustrated in Fig.1a. M D SC perm its to establish this tem perature T<sub>A</sub> at which dynam ics become landscape dom inated (i.e. in MDSC language dom inated by a Tdependent H<sub>nr</sub>) in contrast to the linear response regime (i.e. at high tem peratures when the heat ow is H-rev dom insted with a constant activation energy).

In binary  $Ge_x Se_{1-x}$  glasses, observed variations in  $T_A = T_G$  and  $T_K = T_G$  as a function of  $n_b = 2 + 2x$  are compared to HW predictions in Fig.lb. The  $T_K = T_G$  ( $n_b$ ) results were obtained from a Vogel-Fulcher analysis of viscosity measurements[4]. And one nds the observed and predicted variations in  $T_K = T_G$  ( $n_b$ ) ratio to be in reasonable accord with each other showing a general reduction starting from a value of about 0.9 at  $n_b = 2$  to a value of 0.8 near  $n_b = 2$ :7. Note, how ever, that the broad global minimum in the observed  $T_K = T_G$  ratio near  $n_b = 2$ :4 in not reproduced by the HW approach. More serious is the fact that observed  $T_A = T_G$  values are (i) two orders of

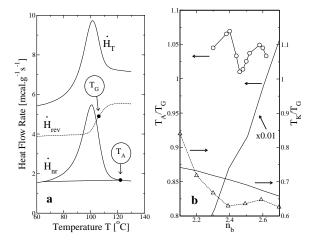

FIG.1: a: M D SC scan of A  $s_{20}Se_{30}$  bulk glass;  $T_G$  is de ned as in exion point of  $H_{\rm rev}$  while  $T_A$  is the end point of the  $H_{\rm nr}$  endotherm .b:  $T_A = T_G$  () and  $T_K = T_G$  (4) for G e-Se glasses. Lines without symbols are HW predictions [1]

m agnitude lower than the HW predictions and (ii) show a globalm inim um near  $n_{\rm b}=2.4$  that is in sharp contrast to the alm ost linear increase (F ig. 1b) predicted by HW . The globalm inim um in  $T_{\rm K}$  =T\_G and  $T_{\rm A}$  =T\_G ratios are features related to self-organization of glasses that are m issing in the HW approach. Clearly features such as inclusion of local structures [3, 5], structural self-organization [5, 6] and non-central forces (bond-bending) are m issing in the theory. Non-bending forces constitute (4n\_b 6)=(5n\_b 6) of the global number of network constraints (e.g. 0.6 at the ideal  $n_b$  = 2.4) indicating that the directional non central angular forces have to be included in a successful theory of network glasses.
