Abstract

Using in-situ angle dispersive X-ray diffraction, we have shown that barium tungstate, which exists in scheelite phase at ambient conditions, transforms to a new phase at $\sim 7 \pm 0.3$ GPa. Analysis of our data based on Le Bail refinement suggests that this phase could be fergusonite and not HgMoO₄ type, which was proposed earlier from the Raman investigations. Beyond ~ 14 GPa, this compound undergoes another phase transformation to a significantly disordered structure. Both the phase transitions are found to be reversible.

1. Introduction

The alkaline earth tungstates, molybdates and vanadates, aside from their geological relevance, are important laser host materials. Therefore, many of these ABO₄ type compounds (A = Ca, Ba, Bi, Sr...) (B = V, Mo, W) have been widely investigated [1-7]. Structurally these compounds exist in several forms, such as scheelite, wolframite, fergusonite, HgMoO₄, etc. [2,8-11]. Though earlier arguments, based either on packing efficiency or higher coordination, etc. [12], suggested wolframite to be a preferred high pressure structure, subsequent experiments have shown a wide variety of structures in the phase diagrams of these compounds. This necessitates a fresh look into some of the earlier studies. BaWO4 is one such compound. At ambient conditions it is known to exist in the scheelite structure, shown in Fig. 1 (tetragonal, I4₁/a, Z = 4). Several recent high pressure studies have shown that the compounds having initial scheelite structure may transform to wolframite [3,13,14], fergusonite [10], HgMoO₄ [5], or other closely related structures. However, previous X-ray diffraction studies on barium tungstate, quenched from 4 GPa and 600 °C, indicated that it transforms irreversibly to a monoclinic phase $(P2_1/n)$, which is distinct from either wolframite or fergusonite structures [15, 16]. Subsequent high pressure Raman scattering by Jayaraman et al. [5], showed that barium tungstate undergoes a reversible first order phase transition around 6.5 ± 0.3 GPa. From the observed abrupt decrease in the frequency of the internal W–O modes, these authors suggested the high pressure structure to be HgMoO₄ type [11]. However, no in-situ X-ray diffraction study has been carried out on this compound. Hence, we have carried out angle-dispersive X-ray diffraction studies on barium tungstate under high pressures, upto 20 GPa.

2. Experimental

High pressure angle dispersive powder X-ray diffraction experiments were carried out employing monochromatized (with graphite (002) monochromator) molybdenum K_{α} radiation from a rotating anode X-ray generator. Finely powdered sample was loaded in a pre-indented steel gasket hole of $\sim 150~\mu m$ diameter in a Mao-Bell kind of diamond

anvil cell. For these experiments either 4:1 methanol—ethanol or 16:3:1 methanol—ethanol—water mixtures were used as pressure transmitters, which are known to freeze into soft solids at ~ 10.4 and ~ 14.5 GPa, respectively [17,18]. The pressure in the gasket hole was determined by monitoring the shift in ruby R-lines [19]. At each pressure the diffraction data was collected for more than 15 h on an imaging plate (IP). One-dimensional diffraction profiles were generated from IP records using FIT2D software [20].

3. Results and discussions

Fig. 2 shows our recorded X-ray diffraction profiles at a few representative pressures. Due to the divergence of the X-ray beam, the recorded diffraction patterns are contaminated by several diffraction peaks from the gasket (marked as G_i in Fig. 2). However, at ambient conditions, 14 diffraction peaks of scheelite–BaWO₄ are clearly discernible and the cell constants for the initial phase are found to be, $a = 5.63 \pm 0.01$ Å and $c = 12.75 \pm 0.01$ Å; which are in fairly good agreement with the published results—a = 5.61 Å, c = 12.71 Å (ICDD card no 43-0646). Our results show that upto \sim 7 GPa, the observed diffraction peaks shift smoothly with pressure. However, at \sim 7 \pm 0.3 GPa, an

Fig. 2. The diffraction patterns of BaWO₄ at various pressures. The diffraction pattern at 0.1 MPa has been indexed to the scheelite phase and the pattern at 9.3 GPa to the fergusonite phase. The arrows mark the observed changes in the diffraction pattern at the completion of the first phase transformation (9.3 GPa), and after the second phase transformation (14 GPa). G_i (i = 1-3) indicate the gasket peaks. The diffraction peak at 10° (#) is the second order (200) diffraction peak of the steel gasket. The gasket steel is primarily the fcc phase. However, it has a small amount of some other phase, which shows up on either side of the G₃ (200) gasket diffraction peak marked as (*). Beyond 10 GPa the gasket undergoes a phase transformation and the diffraction peaks of the fcc phase of the gasket weakens and the intensities of the diffraction peaks marked with the * increase. The diffraction from the gasket is quite strong as the X-ray beam from the rotating anode generator is a diverging beam.

additional diffraction peak emerges close to the (200) diffraction peak (marked with an arrow in Fig. 2). Concomitantly, several diffraction peaks broaden and the intensities of the (312) and (224) peaks redistribute. These observed changes suggest a phase transformation to a lower symmetry structure—broadly supporting the earlier Raman studies of Jayaraman et al. [5]. In addition, the observed coexistence of the scheelite (phase I) and the new phase (phase II) upto 7.7 ± 0.3 GPa, indicate the first order nature of this transformation. On further increase of the pressure, signal to noise ratio of the diffraction peaks deteriorates significantly

beyond 10 GPa. However, at \sim 14 GPa, two new diffraction peaks emerge, one on either side of the diffraction peak at $2\theta \sim 13^{\circ}$. These new peaks, indicated by arrows in Fig. 2, persist upto ~ 20 GPa, the highest applied pressure in these experiments. From the limited diffraction data available beyond 14 GPa, it is difficult to identify the underlying structural modifications. However, it is also possible that BaWO₄ transforms to a disordered crystalline phase (in the sense that amorphous and a poorly crystallized phases coexist, similar to what has been observed in α-FePO₄ [21] and α-AlPO₄ [22]). Since the diffraction peaks remain broad even on the release of pressure below 10 GPa, it is more likely that the broadening and degradation of diffraction pattern is due to a transformation to a disordered crystalline phase. It was observed that the experimental results did not vary with the usage of different pressure transmitters.

Earlier high pressure studies of the scheelite tungstates suggest that the probable space groups of the phase II may be—I2/a (HgMoO₄ or fergusonite), P2/c (wolframite) or $P2_1/n$. The computed diffraction pattern for the $P2_1/n$ space group differs considerably from the observed diffraction pattern of the phase II in terms of positions and intensities of the peaks, and is thus ruled out. Also, a strong diffraction peak of the wolframite structure, expected at $d \approx 4$ Å, is not observed in the phase II. In addition, the intensities of the observed diffraction peaks at d = 2.67 and 2.59 Å differ considerably from the calculated intensities for the wolframite structure. Moreover, as given in Table 1, the observed diffraction peak at d = 1.78 Å and a doublet, observed between 1.59 Å $\leq d \leq$ 1.64 Å, are not ascribable to the wolframite structure (the peak close to $\sim d = 1.59 \,\text{Å}$ would be very broad). These disagreements with the observed results do not support wolframite as a favorable structure of phase II. To evaluate HgMoO₄ and fergusonite structures (space group I2/a), we have analyzed our data with Le Bail fitting [23]. Background corrected diffraction pattern could be reasonably well fitted with the Le Bail method (with $R_{\rm wp} = 0.08$), supporting this assignment of the space group. Further, the comparison of the observed diffraction pattern and the calculated diffraction patterns of the fergusonite phase and HgMoO4 phase, as presented in Table 1, shows that the intensity as well as the d-value of the first diffraction peak of the HgMoO4 structure differs substantially from the observed value. In addition, we do not observe a strong (200) peak of the HgMoO₄ phase. However, for the fergusonite structure, the intensities as well as the d-values match fairly well. Based on these observations, we conclude that the observed diffraction pattern of phase II favors fergusonite structure in comparison with the wolframite and HgMoO₄ structures. Fig. 3 shows the BaWO₄ in the fergusonite phase, generated by using the fractional atomic coordinates of Ref. [10]. In this phase though the W-O are still four coordinated, the WO₄ tetrahedra are significantly deformed. However, ideally the fractional coordinates should be determined by Rietveld analysis, which has not been carried out due to the

Fig. 3. Crystal structure of BaWO₄ in the fergusonite phase (with the fractional atomic coordinates of Ref. [10]). The W atoms are tetrahedrally coordinated to oxygen and ● represent Ba.

contamination of diffraction pattern by the gasket peaks. Further, the comparison of Figs. 1 and 3 shows that the two structures are easily relatable through correlated-displacive atomic motion, i.e. the lattices of alternate layers (along *c*-axis) of the scheelite structure shift in opposite directions to form pairs with neighbor layers.

The observed variation of the lattice constants a and c with pressure is shown in Fig. 4(a)–(c). The solid line is a quadratic fit, which gives

$$a(p) = 5.6257 - 0.0276p + 6.929 \times 10^{-4}p^2 \tag{1}$$

$$c(p) = 12.749 - 0.0987p + 2.002 \times 10^{-3}p^2$$
 (2)

where p is in GPa.

Experimentally determined equation of state, plotted in Fig. 4(d), shows a small volume discontinuity (1.7%) at \sim 7 \pm 0.3 GPa. The P-V data can be analyzed with the help of Birch–Murnaghan (BM) equation of state, viz.

$$P = (3/2)K[(V_0/V)^{7/3} - (V_0/V)^{5/3}][1 - (3/4)(4$$
$$- K')\{(V_0/V)^{2/3} - 1\}]$$
(3)

Where K and K' represent the bulk modulus and its derivative. A least square fit of our data with Eq. (3) gives K = 57 GPa and K' = 3.5 for the scheelite phase.

The anisotropy in compression, as discussed by Angel [24], is also analyzable with the help of the linear variant of BM equation of state. To do so, we can replace V_0/V in Eq. (3) with $(a_0/a)^3$ or $(c_0/c)^3$, respectively, for a and c cell

The volume per formula unit of all the three structures was taken to be equivalent to the observed volume at 8.3 GPa. Since the beta angle is not unique for a particular structure (i.e. it varies from 89.6° [9] to 95.2° [10] for the fergusonite phase; from 89.4° [2] to 94.85° [14] for the wolframite phase etc) we have taken the beta angle equal to 89.6° (Le Bail fit of present study) for all the three structures. The fractional coordinates were taken from the references mentioned above in each column.

lengths. K obtained by fitting this isothermal equation is then one third of the inverse of the linear zero pressure compressibility (β_0) along the chosen axis (where $\beta_0 = l_0^{-1}$ $(\partial l/\partial P)_{p=0}$, l_0 being the cell length at ambient conditions) [24]. For scheelite phase the observed variations in cell parameters (Figs. 4(a)–(c)) give the modulus K_c (i.e., along the c-axis) to be 113 GPa, and K_a (the modulus along the

a-axis) to be 197 GPa. This implies that in the scheelite phase c-axis is almost 1.7 times more compressible than the a-axis. The overall bulk modulus when calculated by the following equation

$$1/K = 2/K_a + 1/K_c$$

is 53 GPa which is slightly less than that calculated by fitting

^a Calculated values are from a (fergusonite) monoclinic unit cell with a = 5.4444 Å, b = 12.2903 Å, c = 5.2358 Å, $\beta = 89.56^{\circ}$, Z = 8 and the fractional coordinates from Ref. [10].

^b For wolframite, the calculations were carried with a = 5.1643 Å, b = 6.2464 Å, c = 5.4303 Å, $\beta = 89.56$ °, Z = 4 and the fractional coordinates from Ref. [2].

[°] The calculations for HgMoO₄ structure were carried out with a = 5.2749 Å, b = 6.194 Å, c = 10.7226 Å, $\beta = 89.56$ °, Z = 8 and the fractional coordinates from Ref. [11].

the P-V data. The compressibility in this material is primarily due to the larger and softer Ba-O bonds (2.78 Å) rather than the shorter and stronger W-O tetrahedral bonds (1.87 Å). Though no direct information is available for BaWO₄, but for a closely related scheelite SrWO₄, the calculated bond stretching and bond bending force constants of W-O are about five times larger than that of Sr-O [6].

On release of pressure from 20 GPa, both the high pressure phases continue to exist upto ~ 3 GPa, indicating a large hysteresis. The existence of hysteresis as well as reversibility between scheelite, fergusonite and disordered crystalline phase imply the first order as well as displacive nature of these phase transformations. It is interesting to note that similar, but temperature induced, reversibility between these two phases has also been observed in BiVO₄, rare earth orthoniobates and orthotantalates [25–28].

4. Conclusions

In-situ high pressure powder X-ray diffraction studies on BaWO₄ show that barium tungstate undergoes a first order phase transition to a new phase at $\sim 7\pm 0.3$ GPa. It has been shown that this new phase could have a structure similar to the monoclinic fergusonite phase. At 14 GPa, it further transforms to a new phase which becomes significantly disordered by ~ 20 GPa. On release of pressure from 20 GPa, the scheelite phase is recovered below 3 GPa, indicating reversible nature of both the transformations. As, in several ABO₄ compounds, similar scheelite-fergusonite phase transformation have been found to be ferro-elastic, it will be interesting to study whether this pressure induced transformation is also driven by a softening of some elastic constants.
