

A distribution function analysis of wealth distribution

Abstract

We develop a general framework to analyze the distribution functions of wealth and income. Within this framework we study wealth distribution in a society by using a model which turns on two-party trading for poor people while for rich people interaction with wealthy entities (huge reservoir) is relevant. At equilibrium, the interaction with wealthy entities gives a power law (Pareto-like) behavior in the wealth distribution while the two party interaction gives a distribution similar to that reported earlier [1, 2].

The distribution of wealth in a nation has been a subject of interest for a long time. An empirical observation due to Pareto [3] states that the higher income group distribution has a power law tail with exponent varying between 2 and 3. As for the lower income group distribution it is exponential or G ibb's like. The G ibb's law has been shown to be obtainable when trading between two people, in the absence of any savings, is totally random [4, 1, 5, 2]. The constant nite savings case has been studied numerically by Chakraborti and Chakrabarti [1] and analytically by us [2]. Furthermore a power law behavior has been reported for the higher income group when the savings are taken to be random [6, 7].

In this paper, we try to identify the processes that lead to the wealth distribution in societies. Our model involves two types of trading processes – microscopic and macroscopic. The microscopic process involves trading between two individuals while the macroscopic one involves trading between an individual and the macro-system. The philosophy is that small wealth distribution is governed by two party trading while the large wealth distribution involves big players interacting with the macro-system. The big players mainly interact with large entities/organizations (which they are not directly part of) such as government (s), markets of other nations, etc. These entities/organizations are treated as making up the macro-system in our model. The macro-system is thus a huge reservoir of wealth. Whereas the poor are mainly involved in trading with other poor individuals. Hence, our model invokes the microscopic channel at small wealths while at large wealths the macroscopic channel gets turned on.

The details of our model are as follows. An individual possessing wealth larger than a cut-off wealth (y_c) trades with a fraction $[(1 - \alpha)]$ with $0 \leq \alpha \leq 1$ of his wealth (y) with the macro-system with the latter putting forth an equal amount of money $[(1 - \alpha)y]$. The trading involves the total sum $[2(1 - \alpha)y]$ being randomly distributed between the individual and the macro-system. Thus on an average the macro-system's wealth is conserved. As regards individuals that possess wealth smaller than y_c they engage in two party trading where two individuals i and j put forth a fraction of their wealth $(1 - \alpha)y_i$ and $(1 - \alpha)y_j$ respectively. Then the total money $(1 - \alpha)(y_i + y_j)$ is randomly distributed between the two. The total money between the two is conserved in the two-party trading process. We assume that probability of trading by individuals having certain money is proportional to the number of individuals with that money.

We will now develop a formalism similar to Boltzmann transport theory so as to obtain the distribution function $f(y; y; t)$ for wealth (y), income (y), and time (t). Similar to Boltzmann's postulate we also postulate a dynamic law of the form

$$\frac{\partial f}{\partial t} = \left(\frac{\partial f}{\partial t} \right)_{\text{ext source}} + \left(\frac{\partial f}{\partial t} \right)_{\text{interaction}} : \quad (1)$$

The first term describes the evolution due to external income sources only and can be written as a continuity equation

$$\left(\frac{\partial f}{\partial t} \right)_{\text{ext source}} = \frac{\partial (yf)}{\partial y} - \frac{\partial (yf)}{\partial y} : \quad (2)$$

We will first analyze the microscopic channel. As was derived earlier on by us (see Ref. [2]), for the case involving only two party interaction with no upper cut-off, the distribution function for the money of a person to lie between y and $y + dy$ is given by

$$f(y) = \frac{\int_0^y dL}{(1 - \alpha)L} \frac{\int_{\max[0; y - (1 - \alpha)L]}^{\infty} dx f(x) f(L - x)}{L} : \quad (3)$$

We will now obtain the above equation within the Boltzmann type transport formalism. If we assume that there is no external income source, then $\left(\frac{\partial f}{\partial t} \right)_{\text{ext source}} = 0$. The second (non-trivial) term can be obtained as follows in terms of a balance equation.

$$\frac{\partial f}{\partial t} = \left(\frac{\partial f}{\partial t} \right)_{\text{interaction}} = \text{gains} - \text{losses} : \quad (4)$$

In the above equation the two terms on the right hand side can be expressed in terms of transition rates $r(y_1; y_2; y_1^0; y_2^0)$ for a pair of persons to go from moneys $y_1 y_2$

to money $y_1^0 y_2^0$. Then we have on assuming that the distribution function is only a function of wealth and time (such as when income is proportional to one's wealth)

$$\frac{\partial f(y_1; t)}{\partial t} = \int_0^L \int_0^L r(y_1^0; y_2^0; y_1 y_2) f(y_1^0; t) f(y_2^0; t) dy_2^0 dy_1^0 - r(y_1; y_2; y_1^0; y_2^0) f(y_1; t) f(y_2; t) dy_2^0 dy_1^0: \quad (5)$$

In the above equation, conservation law requires $y_1 + y_2 = y_1^0 + y_2^0$. Hence in the first integral we treat y_2 as redundant and integrate out with respect to it to yield a normalization constant. Similarly in the second integral y_2^0 is integrated out. Now for the transition rate in the first integral of the above equation we have

$$r(y_1^0; y_2^0; y_1 y_2) / \begin{cases} \frac{1}{(1 - y_1^0 - y_2^0)} & \text{if } y_1^0 \leq y_1 \text{ and } y_1^0 + (1 - y_1) y_2^0 \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

On taking into account the restriction that no one can have negative money and setting $y_1^0 + y_2^0 = L$, the first integral is proportional to

$$\int_{y_1=0}^{L-1} \frac{dL}{(1 - y_1)^L} \int_{y_1^0=0}^{L-y_1} dy_1^0 f(y_1^0) f(L - y_1^0): \quad (7)$$

As regards the second integral, at equilibrium we assume that the transition from y_1 to all other levels is proportional to $f(y_1)$. Also since at equilibrium $\frac{\partial f(y_1; t)}{\partial t} = 0$, we obtain the distribution function to be that given by Eq. (3).

On introducing an upper cut-off y_c for the two party trading, the contribution to the distribution function $f(y)$ from the microscopic channel becomes

$$\int_{y=0}^{L-1} \frac{dL}{(1 - y)^L} \int_{y_1^0=0}^{L-y} dx f(x) f(L - x) [1 - (x - y_c)] [1 - (L - x - y_c)]: \quad (8)$$

Next, we will analyze the macroscopic contribution to the distribution function $f(y)$. The macroscopic contribution to $\frac{\partial f(y_1; t)}{\partial t}$ is given by

$$\left(\frac{\partial f(y_1; t)}{\partial t} \right)_{\text{reservoir interaction}} = \int_0^L r(y_1^0; y_1) f(y_1^0; t) dy_1^0 - \int_0^L r(y_1; y_1^0) f(y_1; t) dy_1^0: \quad (9)$$

Total money involved in trading (between individual and the macro-system) is $2y_1^0(1 - y_1)$. After interaction, the resulting money y_1 of the individual satisfies the following constraints $y_1^0 - y_1 \leq (2 - y_1)y_1^0$. The first transition rate $r(y_1^0; y_1)$ in the above equation is given by

$$r(y_1^0; y_1) / \begin{cases} \frac{1}{2y_1^0(1 - y_1)} & \text{if } y_1^0 \leq y_1 \leq (2 - y_1)y_1^0 \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

As before, at equilibrium the second integral on the other hand is proportional to $f(y_1)$ when only the macroscopic channel is operative.

On taking into account an upper cut-off y_c , the contribution to the distribution function $f(y)$ from the macroscopic channel is

$$\int_{y=(2-y_c)}^y \frac{dx f(x)}{2x(1-x)} \quad (x > y_c): \quad (11)$$

Then $f(y)$ is given by the sum of the two expressions given in Eqs. (8) and (11) for the microscopic and the macroscopic channels respectively. Now it is interesting to note that the solution of the equation

$$f(y) = \int_{y=(2-y_c)}^y \frac{dx f(x)}{2x(1-x)}; \quad (12)$$

is given by $f(y) = cy^n$. To obtain n one then has to solve the equation

$$(2-y_c)^n - n = 2n(1-y_c); \quad (13)$$

and obtains $n = 1; 2$. Only $n = 2$ is a realistic solution because it gives a realistic cumulative probability. It is of interest to note that the solution is independent of

. Next, we would like to mention that we have chosen the trading probability of a person with certain money, whether above the cut-off y_c or below it, is determined purely by the number of people at that money. However, if the interactions above y_c occur with a smaller probability governed by a prefactor then Eq. (12) becomes

$$f(y) = \int_{y=(2-y_c)}^y \frac{dx f(x)}{2x(1-x)}; \quad (14)$$

The solution of the above equation is again a power law of the form $f(y) = cy^n$ with n depending on both β and γ and is plotted in Fig. 1. When $\beta < 1$, at smaller values of γ , there are two solutions for n with the smaller solution being less than unity and at larger values of γ there is only one solution. We have plotted only the larger solution for all values of γ as it is the only realistic solution from a cumulative probability point of view. From Fig. 1 we see that at a given value of $\beta < 1$, as γ increases the value of n and its gradient increases. Furthermore, for a fixed value of γ , as β decreases the value of n increases.

Hence the distribution function, after simplification, is given by

$$f(y) = [1 - (y - (2 - y_c))]^{\frac{1}{\beta}} \left[\int_{y_c}^y \frac{dx f(x)}{2x(1-x)} + \int_{y_c}^y \frac{dx f(x)}{2x(1-x)} \right] + [y - (2 - y_c)]^{\frac{1}{\beta}} \frac{f(y_c)}{y_c^n}; \quad (15)$$

Here it must be pointed out that Eq. (15) yields, as in the case of the purely microscopic channel without an upper cut, when the savings are zero ($\alpha = 0$) and $y \neq 0$

$$f^0(y) = f(y)f(0): \quad (16)$$

In obtaining the above equation we again assumed that the function $f(y)$ and its first and second derivatives are well behaved. Then the solution for small y is given by

$$f(y) = f(0)\exp[-yf(0)]: \quad (17)$$

We solve Eq. (15) iteratively by choosing a trial function, substituting it on the RHS and obtaining a new trial function and successively substituting the new trial functions over and over again on the RHS until the difference between the new trial function f_n and the previous trial function f_p satisfies the accuracy test $\sum_i |f_n(y_i) - f_p(y_i)| \leq 0.005$.

In Fig. 2 we depict, for the zero savings case ($\alpha = 0$) and $\beta = 1$, $f(y)$ with the cut set at ten times the average money per person and the average money person (y_{av}) being set to unity. The distribution, as expected, decays exponentially for small values of y and has power law ($1=y^2$) behavior for $y > 2y_c = 20$. In Fig. 3 we plot $f(y)$ with the cut $y_c = 0.25$, $y_{av} = 1$, and $\beta = 1$ for values of savings fraction $\alpha = 0.1; 0.5; 0.9$. Here the power law behavior ($1=y^2$) takes over for $y > (2/\alpha) = 4$. At smaller values of y they all become zero with the curves at higher α 's approaching zero faster similar to the case of the purely two-party trading model (see Ref. [2]). Next, in Fig. 4 we show the $f(y)$ behavior at values of the cut $y_c = 1; 4; 1; 5; 1; 6$, $y_{av} = 1$, $\alpha = 0.5$, and $\beta = 1$. As expected the $1=y^2$ behavior starts at $y = 1.5y_c$. At smaller values of y the behavior is similar to the purely two-party trading model studied earlier (see Ref. [2]). Lastly, in Fig. 5 we depict $f(y)$ for $y_c = 2$, $y_{av} = 1$, $\alpha = 0.5$, and values of $\beta = 0.8; 0.9$. The power law behavior ($1=y^n$) starts at $y = 3$ with $n = 4(3.209)$ for $\beta = 0.8(0.9)$ [8].

In this paper we introduced a new ingredient – interaction of the rich with wealthy entities and obtain power law behavior similar to Pareto law. On the other hand the wealth distribution of the poorer part of the society is accounted for through two-party trading.

The authors are grateful to B. K. Chakrabarti for useful discussions and support.
