We study the dynamics of epidemic spreading processes aimed at spontaneous dissemination of information updates in populations with complex connectivity patterns. The in uence of the topological structure of the network in these processes is studied by analyzing the behavior of several global parameters such as reliability, e ciency and load. Large scale numerical simulations of update spreading processes show that while networks with hom ogeneous connectivity patterns permit a higher reliability, scale-free topologies allow for a better e ciency.

M odem society increasingly relies on large scale computer and communication networks, such as the Internet. A major challenge in these networks is the developing of reliable algorithms for the dissem ination of information from a given source to thousands, or even millions, of users such as for news and stock exchange updates, mass le transfers and Internet broadcasts [1, 2]. In epidem ic-inspired communication this is achieved by exploring a mechanism analogous to the spreading of infectious diseases in populations [3, 4]. Indeed, epidem ic data dissem ination in computer and communication networks show interesting parallels with both disease propagation in populations and the spread of rum or in social networks. The information spreads like a benign epidem ic through local interaction between nodes which forward the message they receive to a random selection of their peers in the network, until the whole system becomes \infected" with information. The great advantages of epidem ic-style communication is that dissem ination proceeds on a local basis, without any co-ordination from a central organizing body [3, 4]. These protocols are also highly resilient to sudden failure of communication links and nodes.

A relevant result in them athem atical theory of epidem ics is that the spreading of infection in a population is strongly a ected by the patterns of connectivity in the underlying contact networks. In particular in scale-free topologies, characterized by degree distributions with power law behavior P (k) k [5, 6, 7], the statistical relevance of hubs makes the network highly permeable to attacks [8, 9, 10] and the spreading of infections [11] and highlights the need of special immunization strategies. This result suggests that the topology of the underlying computer and communication network might heavily a ect the performance of epidem ic-style data dissemination protocols. Surprisingly, how ever, the impact of network topology on such protocols has not been thoroughly explored, although the results could have an important technological value. Indeed, these protocols potentially in d a large spectrum of application such as mobile communication networks and, more recently, resource discovery in the so-called peer-to-peer system s built on top of the Internet [12], and nally in grid computing [13].

In this paper we de ne a simple epidem ic data dissem ination model and perform a detailed numerical study of the dynam ics of the information propagation in networks with diverse topological properties. Our basic model is a slightly modil ed version of the D aley and K endall (D K) model [14, 15, 16] and it can be considered as the simplest epidem ic algorithm for the updating of distributed databases [4, 17]. We study the main relevant features of the model such as the reliability of the dissem ination process and the amount of trac generated by the dynam ics. Speci cally, we study two di erent prototypical networks: a random hom ogeneous network [18] and a scale-free network. The results obtained point out that in the hom ogeneous topology the epidem ic process provides a more reliable updating of the network. The scale-free topology, on the other hand, allows the algorithm to perform more e ciently in terms of the generated trac. Finally, we com pare the present model with a determ inistic broadcast process and nd that in a wide range of the model param eters the epidem ic algorithm is more e cient.

The model we shall consider is defined in the following way. Each of the N elements of the network can be in three possible states. We call a node holding an update and willing to transmit it a spreader. Nodes that are unaware of the update will be called ignorants while those that already know it but are not willing to spread the update anymore are called still ers. We denote the density of ignorants, spreaders and still ers at time t as (t), (t) and s(t), respectively such that for all t, (t) + (t) + s(t) = 1. The spreading process takes place along the links between spreaders and ignorants. Each time step spreaders contact one (or more) neighboring node. When the spreader contacts an ignorant, the last one turns into a new spreader at a rate 0 on the other hand, the spreader becomes a still er with rate 1 = if a contact with another spreader or a still er takes place [19]. The parameter is called as the considered as the

	1	2	3	4	5	6	8	9
R _{₩ s}	0.831	0.962	0.986	0.994	0.996	0.996	0.998	0.999
R _{BA}	0.368	0.684	0.781	0.874	0.932	0.952	0.977	0.987

TABLE I: Reliability of the epidem ic process, de ned as the density of nodes that has received the update, in the W S and BA networks for di erent values of the parameter \cdot .

average num ber of contacts with spreader/sti er nodes before the spreader turns itself into a sti er. This dynam ics m in ics the attempt of di using an update or num or by nodes which have been recently updated. At the same time, if a node attempts too m any times to communicate the update to nodes which have already received it, it stops the process turning itself into a sti er. In other words, the node realizes that the update has lost its novelty and becomes uninterested in di using it. The present dynamics thus introduces a trade-o in maxim izing the number of updated nodes and m inim izing the number of contacts attempted. O byiously, the e ciency of the spreading process will depend on the rate at which individuals bose interest in further spreading of the num or and the topology of the underlying network.

At the mean-eld level and using the hom ogeneous assumption for the network connectivity pattern, the time evolution of ignorants, spreaders and sti ers is described by the simple set of equations

$$\theta_t (t) = + (t) (t) \frac{1}{-} (t) ((t) + s(t));$$
(2)

where s(t) is obtained by the norm alization condition s(t) = 1 (t) (t) [14, 16]. The dynam ics asymptotically evolves to the state (1) = 0 in which the system is frozen. Noticeably, in random hom ogeneous networks, the density s(1) of elements which are aware of the update is always a nite fraction of the whole population [14, 16]. The hom ogeneous assumption is, how ever, not valid anymore in the case of heterogeneous scale-free networks where it is known that spreading processes may show very dierent properties [11]. In particular, an explicit dependence on the nodes' degree k must be included in the rate equations. While a general analytical solution cannot be obtained in this case, numerical studies on scale-free networks can be used to evaluate the reliability and e ciency of this process in more complex topologies [14, 15].

In the present investigation we used two speci c network models. First we consider the Barabasi-Albert (BA) network [5]. In this model, starting from a set of m_0 nodes, one preferentially attaches each time step a new ly introduced node to moder nodes. The procedure is repeated many times and a network with a power law degree distribution P (k) k with = 3 and average connectivity hki = 2m builds up. This network is a clear example of highly heterogenous network, in that the degree distribution has unbounded uctuations. As a reference of hom ogeneous networks we considered the W atts-Strogatz (W S) network [20] in the case of complete random rew iring. In this case, one starts from a ring with N nodes, each of them connected symmetrically to 2K neighbors. W ith probability p each link connected to a clockwise neighbor is rewired to a random ly chosen node; otherwise it is preserved. A fler enough iterations a random network with an exponential connectivity decay for large k and hki = 2K is generated. H enceforth, we will use $m_0 = m = 3$ for the BA network and p = 1 and K = 3 for the W S model giving hki = 6 for both networks.

We have perform ed large scale num erical simulations by applying repeatedly the nules stated above on BA and WS networks. Initially, $(0) = \frac{N-1}{N}$, $(0) = \frac{1}{N}$, and s(0) = 0, i.e., we start from a single spreader who is willing to spread the update through the network. At every time step, each of the N spreaders contacts all its neighbors in a random sequence, unless during a contact it turns into a sti er. In this case it immediately stops contacting further nodes. This account for the larger transm ission capabilities of high degree nodes that can reach a larger number of neighbors as specified by the heterogeneous network topology. The dynam ical nules of the model are applied in parallel. The sizes of the networks used in the simulations carried out range from N = 10^3 nodes to N = 10^5 nodes and all num erical results have been obtained by averaging at least over 10 di erent networks and 10^3 iterations. The parameter m ay be varying as for the case of communication networks where it is known that the rate of packet loss is not always zero. Nevertheless, without loss of generality, = 1 since it just xes the time scale by rescaling opportunely the rate 1 = 10 and monitor several quantities of interest.

In order to characterize the propagation process we rst focus on the reliability R of the num or propagation de ned as the naldensity s(1) of nodes that have got the update when the process dies out. For obvious practical purposes, any algorithm or process that emulates an e cient spreading of a given message or data packet will try to raise as

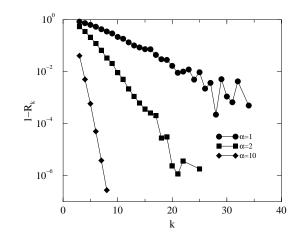

FIG.1: Relative density of ignorants 1 R_k as a function of their connectivity k at the end of the spreading process in SF networks for di erent values of the parameter The size of the network is always N = 10⁴ nodes.

m uch as possible this m agnitude. In Table I we report the reliability of the spreading process for the BA network and the random graph generated with the W S algorithm with p = 1 for several values of the parameter . As noticed previously [15], in the W S network the num ber of sti ers at the end of the process is already high even for = 1, and the BA network appears less reliable. In general, it results that hom ogeneous networks allows a larger reliability R to epidem ic updating processes. This is not straightforw and and one m ay think that the existence of hubs in scale-free networks helps propagate the num or. However, a closer look at the spreading dynam ics tells us that the presence of hubs introduces con icting e ects in the dynam ics. W hile hubs m ay in principle reach a larger number of nodes, spreader-spreader and spreader-sti er interactions get favored on the long run. Indeed, it is very unlikely that a hub in the spreader state contacts all its ignorant neighbors before turning into a sti er. Once a few hubs are turned into sti ers m any of the neighboring nodes could be isolated and never get the update. In this sense, hom ogeneous networks allow for a m ore capillary di usion of the update, since all nodes contribute equally to the m essage-passing. This is opposite to what happens in the usual epidem ic spreading model in heterogeneous networks m odels. These m odels lack of an infected recovery rate induced by neighbors already infected and fully exploit the advantage of hub's large degree [11].

The previous discussion, how ever, refers only to average properties. In SF networks the connectivity distribution is highly heterogeneous and it is interesting to have a more detailed insight on the reliability of the process for di erent connectivity classes. It may be particularly relevant that a higher R corresponds to the highly connected nodes, the hubs, which have a dom inant role in the system. Figure 1 shows the behavior of the reliability R_k m easured as a function of the nodes connectivity k. This amounts to the relative density of nodes with connectivity k that have received the update and it is measured as $R_k = h_{N_k}^{S_k} i$, where S_k and N_k denote the total number of sti ers and the total number of nodes with degree k, respectively. The hi represents the average over m any realizations. The results con m that during the spreading dynam ics it is very likely that highly connected nodes are reached by the update. In fact 1 R_k decreases exponentially with k and very high levels of reliability are obtained well before the natural cut-o of the network (k_{max} 10²) even for moderate values of . This is an interesting feature signaling that heterogeneous topologies can be considered reliable as far as the "hubs" are concerned. We should note, how ever, that since the reliability is not a model independent quantity, this result m ight depend upon the speci c details of the num or algorithm.

In general, one does not only want to have high reliability levels, but also the lowest cost in terms of network load [4, 17]. This is generally achieved by in posing the minimum possible load to the network. Here, we dene the load L in posed to the network as the number of contacts established per node, i.e., how many messages on average each node sends to its neighbors in order to propagate the update. By using this quantity, an obvious denition of the globale ciency E of the whole process is represented by the number of individuals who have got the update per unit of bad, $E = \frac{R}{L}$. Its physical meaning is straightforward: the e ciency is equal to the fraction of \useful messages" (number of sites reached by the num or) over total \load" in posed to the system. In Fig. 2, we report the behavior of the e ciency of the spreading process as a function of . In this case, the scale-free topology appears the most e cient for data dissemination. Indeed, the relative di erence between SF and W S networks in global e ciency is larger than 10% up to values of = 5. This can be appreciated also by looking at the inset in Fig. 2. For both topologies the load on the network grows with , but the load in posed on SF networks is always smaller than on W S nets. Finally, it is interesting to compare the epidem ic algorithm e ciency with those of the sin plest broadcast

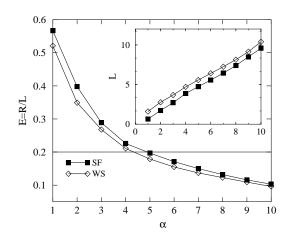

FIG.2: E ciency of the rum or spreading process as a function of in networks of size N = 10⁴. Results are compared with the e ciency of the basic broadcast algorithm that is represented by the thick line. The inset shows the growth of the bad generated as a function of the parameter .

strategy. This strategy essentially consists of a determ inistic message-passing of each element to all its neighbors except the one from which the rst update has been received. This way, a reliability R = 1 is achieved since all nodes are surely contacted. In this case, the load is simply given by hki 1. In the case of networks with hki = 6 as the one used in the present study, the e ciency of the broadcast strategy is therefore E = 0.2. It is interesting to note that in both the BA and the W S case, the epidem is algorithm achieve a better e ciency for a wide range of values of the parameter . This indicates that epidem is algorithm s can provide attractive alternatives to broadcast solutions so far as the e ciency is concerned.

It is worth stressing that we are considering strategies in which the nodes do not have mem ory; i.e. they may try to resend a message to a node that has been contacted before. It is possible, how ever, to conceive di erent dynam ics of the updating spreading strategies in which a trade-o between the mem ory introduced in the process and the optim ization of reliability and e ciency is opportunely chosen. O ther options rely on a careful tuning of the local message sending dynam ics. For instance, we considered the case in which each spreader contacts only one node at each time step, reducing the elects of the hubs. This simple change allows for higher levels of e ciency, how ever, at the price of a much lower reliability. In general, thus it is possible to devise and tailor di erent processes that optim ize one or more features of the update spreading on a given topology. We defer a more detailed study of this issue to future work.

In sum mary, we have studied the e ect of the complex topological properties of many real networks in epidem ic strategies for the communication of updates. The obtained results stimulate the seeking of heuristics and analytical methods to optimize epidem ic algorithms taking into account the specie c topology of the underlying network. These studies may have a large impact in technological and communication networks where the use of num or-like algorithms might become a practice for data dissemination, reliable group communication or replicated database maintenance. Finally, they might provide a deeper understanding for social phenomena such as the spreading of new ideas in a population or the e ciency of marketing campaigns.
