N eural cryptography is based on a competition between attractive and repulsive stochastic forces. A feedback mechanism is added to neural cryptography which increases the repulsive forces. Using num erical simulations and an analytic approach, the probability of a successful attack is calculated for di erent model parameters. Scaling laws are derived which show that feedback in proves the security of the system. In addition, a network with feedback generates a pseudorandom bit sequence which can be used to encrypt and decrypt a secret message.

I. IN TRODUCTION

N eural networks learn from exam ples. W hen a system of interacting neurons adjusts its couplings to a set of externally produced exam ples, this network is able to estim ate the rule which produced the exam ples. The properties of such networks have successfully been investigated using m odels and m ethods of statistical physics [1, 2].

Recently this research program has been extended to study the properties of interacting networks [3, 4]. Two networks which learn the examples produced by their partner are able to synchronize. This means that after a training period the two networks achieve identical time dependent couplings (synaptic weights). Synchronization by mutual learning is a phenom enon which has been applied to cryptography [5, 6].

To send a secret message over a public channel one needs a secret key, either for encryption, decryption, or both. In 1976, Die and Hellm ann have shown how to generate a secret key over a public channel without exchanging any secret message before. This method is based on the fact that | up to now | no algorithm is known which nds the discrete logarithm of large num bers by feasible computer power [7].

R ecently it has been shown how to use synchronization of neural networks to generate secret keys over public channels [5]. This algorithm, called neural cryptography, is not based on number theory but it contains a physicalm echanism : The competition between stochastic attractive and repulsive forces. When this competition is carefully balanced, two partners A and B are able to synchronize whereas an attacking network E has only a very low probability to nd the common state of the communicating partners.

The security of neural cryptography is still being debated and investigated [8, 9, 10, 11, 12]. In this paper we introduce a mechanism which is based on the generation of inputs by feedback. This feedback mechanism increases the repulsive forces between the participating networks, and the amount of the feedback, the strength of this force, is controlled by an additional parameter of

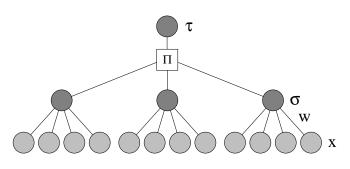

FIG.1: A tree parity machine with K = 3 and N = 4.

ourmodel.

A measure of the security of the system is the probability P_E that an attacking network is successful. We calculate P_E obtained from the best known attack [8] for di erent model parameters and search for scaling properties of the synchronization time as well as for the security measure. It turns out that feedback in proves the security signi cantly, but it also increases the e ort to nd the common key. When this e ort is kept constant, feedback only yields a sm all in provement of security.

II. REPULSIVE AND ATTRACTIVE STOCHASTIC FORCES

The m athem aticalm odel used in this paper is called a tree parity m achine (TPM), sketched in Fig.1. It consists of K di erent hidden units, each of them being a perceptron with an N-dimensional weight vector w_k. When a hidden unit k receives an N-dimensional input vector x_k it produces the output bit

$$k = \operatorname{sgn}(w_k \quad kx): \tag{1}$$

The K hidden units $_{\rm k}$ de ne a common output bit of the total network by

$$= \sum_{k=1}^{Y^{k}} k :$$
 (2)

In this paper we consider binary input values $x_{k;j} \ge f$ f 1;+ 1g and discrete weights $w_{k;j} \ge f$ L; L+1; ...;L 1;Lg, where the index j denotes the N components and k the K hidden units.

Each of the two communicating partners A and B has its own network with an identical TPM architecture. Each partner selects random initial weight vectors w_k^A (t = 0) and w_k^B (t = 0).

Both of the networks are trained by their mutual output bits $^{\rm A}$ and $^{\rm B}$. At each training step, the two networks receive common input vectors x_k and the corresponding output bit of its partner. We use the following learning rule.

- If the output bits are di erent, ^A € ^B, nothing is changed.
- (2) If ^A = ^B only the hidden units are trained which have an output bit identical to the common output, ^{A = B}_k = ^{A = B}_k.
- (3) To adjust the weights we consider three di erent learning rules.

(i) Anti-Hebbian learning

$$w_{k}^{+} = w_{k} \qquad x_{k} (k) (A^{AB}):$$
 (3)

(iii) Hebbian learning

$$w_{k}^{+} = w_{k} + x_{k} (k) (A^{B})$$
 (4)

(iii) Random walk

$$w_{k}^{+} = w_{k} + x_{k} (k) (A^{AB}):$$
 (5)

If any component $w_{k;j}$ moves out of the interval L;:::;L, it is replaced by sgn $(w_{k;j})$ L.

Note that for the last nule, the dynam ics of each component is identical to a random walk with rejecting boundaries. The only difference to usual random walks is that the dynam ics is controlled by the 2K global signals ${}^{A=B}_{k}$ which, in turn, are determined by the ensemble of random walks. Two corresponding components of the weights of A and B receive an identical input $x_{k;j}$, hence they move into the same direction if the control signal allows both of them the move. As soon as one of the two corresponding components hits the boundary their mutual distance decreases. This mechanism nally leads to complete synchronization, w_k^A (t) = w_k^B (t) for all t t_{sync} .

On average, a common step leads to an attractive force between the corresponding weight vectors. If, how ever, only the weight vector of one of the two partners is changed the distance between corresponding vectors increases, on average. This may be considered as a repulsive force between the corresponding hidden units.

A learning step in at least one of the K hidden units occurs if the two output bits are identical, $^{A} = ^{B}$. In this case, there are three possibilities for a given pair of hidden units:

- (1) an attractive move for ${}^{A}_{k} = {}^{B}_{k} = {}^{A=B}$;
- (2) a repulsive move for $\frac{A}{k} \in \frac{B}{k}$;
- (3) and no move at all for ${}_{k}^{A} = {}_{k}^{B} \in {}^{A=B}$.

W e want to calculate the probabilities for repulsive and attractive steps [8, 13]. The distance between two hidden units can be de ned by their mutual overlap

$$_{k} = \frac{q \frac{w_{k}^{A}}{w_{k}^{A}} \frac{q}{w}}{w_{k}^{B}} \frac{w_{k}^{B}}{w_{k}^{B}} \frac{w_{k}^{B}}{w_{k}^{B}} \frac{w_{k}^{B}}{w_{k}^{B}}} :$$
(6)

The probability $_k$ that a common random ly chosen input x_k leads to a di erent output bit $_k^A \notin _k^B$ of the hidden unit is given by [2]

$$_{k} = \frac{1}{-} \arccos_{k} : \qquad (7)$$

The quantity $_k$ is a measure of the distance between the weight vectors of the corresponding hidden units. Since di erent hidden units are independent, the values $_k$ determ ine also the conditional probability P_r for a repulsive step between two hidden units given identical output bits of the two TPM s. In the case of identical distances, $_k =$, one nds for K = 3

$$P_{r} = P\left(\begin{smallmatrix} A \\ k \end{smallmatrix} {}^{A} {}^{B} j \end{smallmatrix} {}^{A} {}^{A} {}^{B} j \end{smallmatrix} {}^{A} {}^{B} \right)$$
$$= \frac{2(1)^{2}}{(1)^{2} + 3(1)^{2}} : \qquad (8)$$

On the other side, an attacker E m ay use the same algorithm as the two partners A and B. Obviously, it will m ove its weights only if the output bits of the two partners are identical. In this case, a repulsive step between E and A occurs with probability $P_r = w$ here now is the distance between the hidden units of E and A.

Note that for both the partners and the attacker one has the important property that the networks remain identical after synchronization. W hen one has achieved

= 0 at some time step, the distance remains zero forever, according to the previous equations for P_r . However, although the attacker uses the same algorithm as the two partners, there is an important di erence: E can only listen but it cannot in uence A or B. This fact leads to the di erence in the probabilities of repulsive steps; the attacker has always more repulsive steps than the two partners. For small distances 1, the probability P_r increases linear with the distance for the attacker but quadratic for the two partners. This di erence between learning and listening leads to a tiny advantage of the partners over an attacker. The subtle competition between repulsive and attractive steps makes cryptography feasible.

On the other side, there is always a nonzero probability P_E that an attacker will synchronize, too [11]. For neural cryptography, P_E should be as small as possible. Therefore it is useful to investigate synchronization for di erent models and to calculate their properties as a function of the model parameters.

Here we investigate a mechanism which decreases $P_{\rm E}$, namely we include feedback in the neural networks. The input vectors x_k are no longer common random numbers, but they are produced by the bits of the corresponding hidden units. Therefore the hidden units of the two partners no longer receive an identical input, but two corresponding input vectors separate with the number of training steps. To allow synchronization, one has to reset the two inputs to common values after some time interval.

For nonzero distance > 0, this feedback m echanism creates a sort of noise and increases the number of repulsive steps. A fler synchronization = 0, feedback w ill produce only identical input vectors and the networks m ove w ith zero distance forever [14].

Before we discuss synchronization and several attacking scenarios, we consider the properties of the bit sequence generated by a TPM with feedback.

III. BIT GENERATOR

We consider a single TPM network with K hidden units, as in the preceding section. We start with K random input vectors x_k . But now, for each hidden unit k and for each time step t, the input vector is shifted and the output bit $_k$ (t) is added to its rst component [16]. Simultaneously, the weight vector w_k is trained according to the anti-H ebbian rule, Eq. (3). Consequently, the bit sequence (t) generated by the TPM is given by the equation

$$(t) = \begin{cases} 0 & 1 \\ X^{N} & X^{N} \\ sgn @ w_{k;j} (t)_{k} (t j)^{A} : \end{cases}$$
(9)

Sim ilar bit generators were introduced in R ef. [17] and the statistical properties of their generated sequences were investigated [18]. Here we study the corresponding properties for our TPM with discrete weights.

The TPM network has $2^{K N}$ possible input and $(2L + 1)^{K N}$ weight vectors. Therefore our determ inistic nite state machine can only generate a periodic bit sequence whose length 1 is limited by $(4L + 2)^{K N}$.

Our numerical simulations show that the average length hli of the period indeed increases exponentially fast with the size K N of the network, but it is much smaller than the upper bound. For K = 3 and L > N we nd hli / $(2:69)^{3N}$, independent of the number L of weight values.

The network takes some time before it generates the periodic part of the sequence. We nd that this transient time also scales exponentially with the system size K N. This means that, for su ciently large values of N, say N 100, any simulation of the bit sequence remains in the transient part and will never enter the cycle.

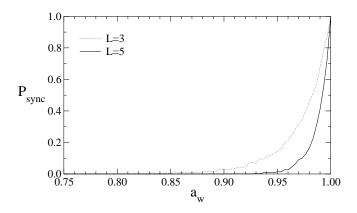

FIG. 2: Probability P_{sync} as a function of the fraction a_w of initially known weights, calculated from 1000 simulations with K = 3 and N = 100.

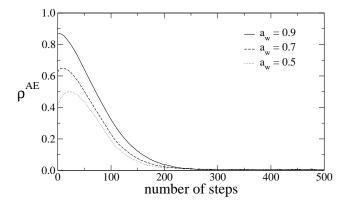

FIG.3: The average overlap between student and generator as a function of the number of steps for $K\ =\ 3,\,L\ =\ 5,$ and $N\ =\ 100$.

The bit sequence generated by a TPM with K > 2 cannot be distinguished from a random bit sequence. For K = L = 3 we have num erically calculated its entropy and found the value $\ln 2$ as expected from a truly random bit sequence. In addition, we have perform ed several tests on random ness as described by K nuth [19]. We did not nd any correlations between consecutive bits; the bit sequence passed all tests on random ness within strict con dence levels.

A lthough the bit sequence passed m any known tests on random numbers we know that it is generated by a neural network. Does this knowledge help to estimate correlations of the sequence and to predict it? In fact, for a sequence generated by a perceptron (TPM with K = 1), another perceptron trained on the sequence could achieve an overlap to the generator β].

Consider a bit sequence generated by a TPM with the anti-Hebbian rule. Another TPM (the \student") is trained on this sequence using the same rule. In addition, if the output bit disagrees with the corresponding bit of the sequence, we use the geom etric m ethod of R ef. [8] to perform a training step. Figures 2 and 3 show that for K = 3 hidden units, it is not possible to obtain an overlap to the generating TPM by learning the sequence. Only if the initial overlap between the generator and the student is very large there is a nonzero probability P_{sync} that the student will synchronize with the generator. If it does not synchronize, the overlap between student and generator decays to zero.

Sum m arizing, a TPM network generates a pseudorandom bit sequences which cannot be predicted from part of the sequence. As a consequence, for cryptographic applications, the TPM can be used to encrypt and decrypt a secret m essage after it has generated a secret key.

IV. SYNCHRONIZATION

As shown in the preceding section, a TPM cannot learn the bit sequence generated by another TPM since the two input vectors are completely separated by the feedback mechanism. This also holds for synchronization by mutual learning: W ith feedback, two networks cannot be attracted to an identical time dependent state. Hence, to achieve synchronization, we have to introduce an additional mechanism which occasionally resets the two inputs to a comm on vector. This reset occurs whenever the system has produced R di erent output bits, ^A (t) \in ^B (t). For R = 0 we obtain synchronization without feedback, which has been studied previously, and for large values of R the system does not synchronize. Accordingly, we have added a new parameter in our algorithm which increases the synchronization time as well as the di culty to attack the system . In the following two sections, we investigate synchronization and security of the TPM with feedback quantitatively.

W e consider two TPM sA and B which start with different random weights and common random inputs. The feedback mechanism is de ned as follows.

- (i) A fler each step t the input is shifted, $x_{k;j}$ (t + 1) = $x_{k;j-1}$ (t) for j > 1.
- (ii) If the output bits agree, ^A (t) = ^B (t), the output of each hidden unit is used as a new input bit, $x_{k;1}$ (t + 1) = $_k$ (t), otherwise all K pairs of input bits $x_{k;1}$ (t) are set to common public random values.
- (iii) A fler R steps with di erent output, ^A (t) \in ^B (t), all input vectors are reset to public common random vectors, $x_{k;i}^{A}$ (t+ 1) = $x_{k;j}^{B}$ (t+ 1).

Feedback creates correlations between the weights and the inputs. Therefore the system becomes sensitive to the learning rule. We nd that only for the anti-H ebbian rule, Eq. (3), the components of the weights have a broad distribution. The entropy per component is larger than 99% of the maxim alvalue ln (2L + 1). For the H ebbian or random walk rule, the entropy is much sm aller, because

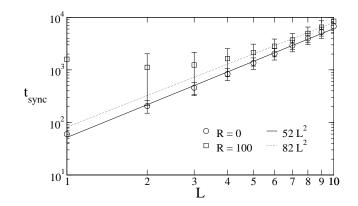

FIG.4: A verage synchronization time t_{sync} and its standard deviation as a function of L, found from 10 000 simulation runs with K = 3 and N = 10000. The line $52L^2$ is a result of linear regression for R = 0.

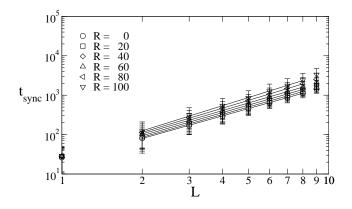

FIG. 5: The synchronization time t_{sync} and its standard deviation as a function of L, averaged over 10 000 runs of the iterative equations for K = 3.

the values of the weights are pushed to the boundary values L. Therefore the network with the anti-H ebbian rule o ers less information to an attack than the two other rules.

In Fig. 4 we have num erically calculated the average synchronization time as a function of the number L of components for the anti-H ebbian nule. Obviously, there is a large deviation from the scaling law $t_{\rm sync}$ / L² as observed for R = 0. Our simulations for larger values of N, which are not included here, show that there exist strong nite size e ects which do not allow to derive a reliable scaling law from the num erical data.

Fortunately, the limit N ! 1 can be performed analytically. The simulation of the K N weights is replaced by a simulation of an (2L + 1) (2L + 1) overlap matrix $f_{a,b}^k$ for each hidden unit k which measures the fraction of weights which are in state a for the TPM A and in state b for B [13, 20].

W e have extended this theory to the case of feedback. A new variable $_{k}$ (t) is introduced which is de ned as the fraction of input components $x_{k,i}$ which are dimensioned be-

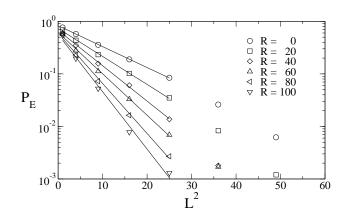

FIG.6: The success probability $P_{\rm E}$ as a function of L , averaged over 10 000 simulations with K = 3 and N = 1000.

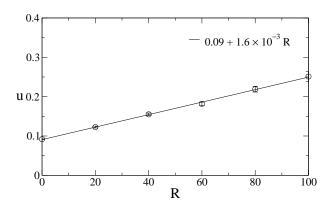

FIG.7: The coe cient u as a function of the feedback parameter R, calculated from the results shown in Fig.6.

tween the corresponding hidden units of A and B. This variable changes with time, and it in uences the equation of motion for the overlap matrix $f^k_{a,b}\left(t\right)$. Details are described in the Appendix.

Figure 5 shows the results of this sem ianalytic theory. Now, in the lim it of N \mid 1, the average synchronization time can be tted to increase with a power of L, roughly proportional to L^2 . The data indicate that only the prefactor but not the exponent depends on the strength R of the feedback; the prefactor seems to increase linearly with R.

Hence, if the network is large enough, feedback has only a small e ect on synchronization. In the following section we investigate the e ect of feedback on the security of the network: How does the probability that an attacker is successful depend on the feedback parameter R?

V. ENSEM BLE OF ATTACKERS

Up to now, the most successful attack on neural cryptography is the geometric attack [8, 11]. The attacker E uses the same TPM with an identical training step as

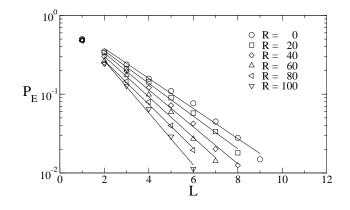

FIG.8: The success probability $P_{\rm E}$ as a function of L, found from 10 000 runs of the iterative equations for K = 3.

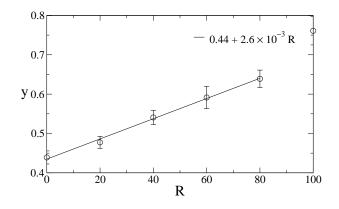

FIG.9: The coe cient y as a function of the feedback parameter R, calculated from the results shown in Fig.8.

the two partners. That means, only for $^{A} = ^{B}$ the attacker performs a training step. When its output bit E agrees with the two partners, the attacker trains the hidden units which agree with the common output. For $^{E} \in ^{A=B}$, how ever, the attacker rst inverts the output bit $_{k}$ for the hidden unit with the sm allest absolute value of the internal eld and then performs the usual training step.

For the geom etric attack the probability $P_{\rm E}$ that an attacker synchronizes with A and B is nonzero. Consequently, if the attacker uses an ensemble of su ciently m any networks there is a good chance that at least one of them will not the secret key.

We have simulated an ensemble of attackers using the geometric attack for the two TPM s with feedback and anti-Hebbian learning rule. Of course, each attacking network uses the same feedback algorithm as the two partner networks. Figure 6 shows the results of our num erical simulations. The success probability P_E decreases with the feedback parameter R. For the model parameters shown in Fig.6 we nd that P_E can be tted to an exponential decrease with L²,

$$P_E / e^{uL^2} :$$
 (10)

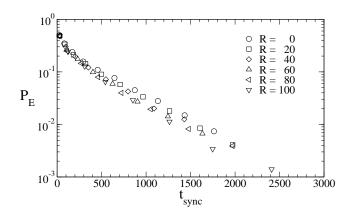

FIG.10: The success probability P_E as a function of the average synchronization time t_{sync} , calculated from the results shown in Figs. 5 and 8.

The coe cient u increases linearly with R, as shown in Fig. 7. The scaling [Eq. (10)], however, is a nite size e ect. For large system sizes N, the success probability decreases exponentially with L instead of L^2 ,

$$P_E / e^{YL} :$$
 (11)

This can be seen from the limit N ! 1 which can be performed with the analytic approach of the preceding section. Now the dynamics of the system is described by a tensor $f_{a,b;e}^k$ for the three networks A, B, and E and corresponding variables A_k^{A} ; B_k^{B} ; E_k^{E} . Details are given in the Appendix.

Figure 8 indicates the exponential scaling behavior [Eq. (11)] for several values of R. The coe cient y increases linearly with R, as shown in Fig. 9.

These results show that feedback in proves the security of neural cryptography. The synchronization time, on the other side, increases, too. Does the security of the system in prove for constant e ort of the two partners?

This question is answered in Fig. 10 which shows the probability $P_{\rm E}\,$ as a function of the average synchronization time, again for several values of the feedback parameter R . On the logarithm ic scale shown for $P_{\rm E}$, the security does not depend m uch on the feedback. For constant e ort to nd the secret key, feedback yields a sm all im provement of security, only.

VI. CONCLUSIONS

N eural cryptography is based on a delicate com petition between repulsive and attractive stochastic forces. A feedback m echanism has been introduced which am pli es the repulsive part of these forces. We nd that feedback increases the synchronization time of two networks and decreases the probability of a successful attack.

The num erical simulations up to $N = 10^5$ do not allow to derive reliable scaling laws, neither for the synchronization time nor for the success probability. But the lim it N $\,!\,\,1\,$ which can be perform ed analytically indicates that the scaling laws with respect to the number L of component values are not changed by the feedback, only the respective coe cients are modi ed. The average synchronization time increases with L^2 while the probability P_E of a successful attack decreases exponentially with L, for huge system sizes N .

A coordingly, the security of neural cryptography is in proved by including feedback in the training algorithm. But simultaneously the e ort to nd the common key rises. We nd that for a xed synchronization time, feedback yields a sm all improvement of security, only.

A fler synchronization, the system is generating a pseudorandom bit sequence which passed all tests on random numbers applied so far. Even if another network is trained on this bit sequence it is not able to extract som e inform ation on the statistical properties of the sequence. C onsequently, the neural cryptography cannot only generate a secret key, but the same system can be used to encrypt and decrypt a secret m essage, as well.

APPENDIX A:SEMIANALYTICAL CALCULATION FOR SYNCHRONIZATION WITH FEEDBACK

In this appendix we describe our extension of the sem ianalytic calculation [13, 20] to the case of feedback.

The e ect of the feedback mechanism depends on the fraction of new ly generated input elements $x_{k;j}$ per step and hidden unit. In the numerical simulations presented in this paper is equal to N⁻¹. In this case the e ect of the feedback mechanism vanishes in the limit N ! 1. But it is also possible to generate several input elements $x_{k;j}$ per hidden unit and step. For that purpose one can multiply the output bit $_k$ with N random numbers z 2 f 1;+1g. As we want to compare the results of the semianalytical approach with simulations for N = 1000, we set = 10⁻³ in the following calculations.

In the case of two TPM s the developm ent of the input noise k is given by

$${}^{+}_{k} = (1)_{k} + ({}^{A B}_{k k}) ({}^{A B}) : (A1)$$

At the beginning and after R steps with $A \in B$ all variables k are set to zero (according to the algorithm described in Sec. IV).

The input noise generated by the feedback mechanism a ects the output of the hidden units. An input element with $x_{k;j}^B = x_{k;j}^B$ causes the same output k_k^B as a change of sign in $w_{k;j}^B$ together with equal inputs for both A and B. Therefore the probability $k_{k;e}$ that two hidden units with overlap k_k and input error k_k disagree on the output bit is given by

$$k_{k,e} = \frac{1}{4} \arccos(1 \ 2_{k})_{k}$$
: (A2)

The distance $_{k;e}$ between the hidden units of A and B is used to choose the output bits $_{k}^{A}$ and $_{k}^{B}$ with the correct probabilities in each step [13, 20].

The feedback mechanism in uences the equation of motion for the overlap matrix $f_{a,p}^k$, too. Here we use additional variables $m = (m m) (A^B)$ to determine if the weights of hidden unit k in the TPM of m 2 fA;B;Eg change (m m = 1) or not (m m = 0). Therefore we are able to describe the update of elements $f_{a,p}^k$ away from the boundary (L < a;b < L) in only one equation:

$$f_{a,b}^{k+} = \frac{1}{2} \left(f_{a+}^{k} + f_{k}^{a} + f_{k}^{b+} + f_{a}^{k} + f_{k}^{b} +$$

The second term in Eq. (A3) which is proportional to $_k$ shows the repulsive e ect of the feedback mechanism. Sim ilar equations can be derived for elements on the boundary.

In the limit N ! 1 the number of steps required to achieve full synchronization diverges [9]. Because of that one has to de ne a criterion which determ ines synchronization in order to analyze the scaling of t_{sync} using semianalytic calculations. As in Ref. [13] we choose the synchronization criterion $AB = \frac{1}{3} \begin{bmatrix} F & AB \\ K = 1 \end{bmatrix} \begin{bmatrix} AB \\ K \end{bmatrix} 0.9$.

In order to analyze the geom etric attack in the lim it N ! 1 one needs to extend the sem ianalytical calculation to three TPM s. In this case the developm ent of the input noise is given by the following equations:

$$\begin{array}{rcl} {}^{A\,+}_{k} & = & \left(\begin{array}{cc} {}^{A} {}^{B} {}^{B} {}^{}_{k} {}^{}_{$$

A nalogical to Eq. (A 2) the distance ${}^{m\,n}_{k;e}$ between two hidden units can be calculated from the overlap ${}^{m\,n}_{k}$ and the variables ${}^{m}_{k}$ and ${}^{n}_{k}$:

$$m_{k,e}^{mn} = \frac{1}{2} \arccos(1 \ 2_{k}^{m} \ 2_{k}^{n})_{k}^{mn} :$$
 (A7)

But for the geom etric attack the attacker E needs to know the local elds h^E_k . The joint probability distribution of h^A_k , h^B_k and h^E_k is given by [13]

$$P(h_{k}^{A};h_{k}^{B};h_{k}^{E}) = \frac{e^{(1=2)(h_{k}^{A};h_{k}^{B};h_{k}^{E})C_{k}^{-1}(h_{k}^{A};h_{k}^{B};h_{k}^{E})^{T}}}{(2)^{3} \det C_{k}}$$
(A 8)

The covariance matrix in this equation describes the correlations between the three neural networks:

$$C_{k} = \begin{pmatrix} 0 \\ Q_{k}^{A} \\ R_{k;e}^{AB} \\ R_{k;e}^{AB} \\ R_{k;e}^{BE} \\ R_{k;e}^{AB} \\ R_{k;e}^{BE} \\ R_{k;e}^{BE} \\ R_{k;e}^{BE} \\ R_{k;e}^{BE} \\ R_{k;e}^{AB} \\ R_{k;e}^$$

From the tensor $f_{a,b;e}^k$ and the variables $\frac{m}{k}$ one can easily calculate the elements of C_k :

$$Q_{k}^{A} = \begin{array}{c} X^{L} \\ a^{2} f_{a,b;e}^{k}; \end{array}$$
 (A 10)

$$Q_{k}^{B} = \begin{matrix} X^{L} \\ b^{2} f_{a,b,e}^{k} \end{matrix}$$
 (A 11)

$$Q_{k}^{E} = \frac{X^{L}}{e^{2} f_{a,b;e}^{k}}; \qquad (A 12)$$

(

$$R_{k,e}^{AB} = (1 \quad 2_{k}^{A} \quad 2_{k}^{B}) \qquad abf_{a,b,e}^{k}; (A13)$$

$$R_{k;e}^{AE} = (1 \quad 2_{k}^{A} \quad 2_{k}^{E}) \quad \operatorname{aef}_{a;b;e}^{k}; (A 14)$$

We use a pseudorandom number generator to determine the values of h_k^A , h_k^B , and h_k^E in each step. The application of the rejection method [21] ensures that the local elds have the right joint probability distribution P (h_k^A ; h_k^B ; h_k^E). Then the output bits $_k^m$ of the hidden units are given by $_k^m = \operatorname{sgn}(h_k^m)$. If $^A = ^B \in ^E$ the hidden unit k with the smallest absolute local eld h_k^E j is searched and its output $_k^E$ is inverted (geom etric attack). A flerwards the usual training of the neural networks takes place.

The equation of motion for tensor elements $f_{a,b;e}^k$ away from the boundary (L < a;b;e < L) is given by

$$f_{a;b;e}^{k+} = \frac{1 \quad \stackrel{A}{k} \quad \stackrel{B}{k} \quad \stackrel{E}{k}}{2} f_{a}^{k} \quad \stackrel{A}{k} \stackrel{A}{k} \stackrel{B}{k} \stackrel{E}{k} f_{a}^{k} \quad \stackrel{A}{k} \stackrel{B}{k} \stackrel{E}{k} \stackrel{E}{k} f_{a}^{k} \quad \stackrel{A}{k} \stackrel{B}{k} \stackrel{E}{k} \stackrel{E}{k} f_{a}^{k} \quad \stackrel{A}{k} \stackrel{B}{k} \stackrel{E}{k} \stackrel{E}{k} f_{a}^{k} \quad \stackrel{A}{k} \stackrel{B}{k} \stackrel{E}{k} \stackrel$$

Sim ilar equations can be derived for elements on the boundary. An attacker is considered successful if one of the conditions AE 0.9 or BE 0.9 is achieved earlier than the synchronization criterion AB 0.9.
