We study the form ation of an electronic nem atic phase characterized by a broken point-group symmetry in interacting fermion systems within the weak coupling theory. As a function of interaction strength and chemical potential, the phase transition between the isotropic Fermi liquid and nem atic phase is rst order at zero temperature and becomes second order at a nite temperature. The transition is present for all typical, including quasi-2D, electronic dispersions on the square lattice and takes place for arbitrarily small interaction when at van Hove lling, thus suppressing the Lifshitz transition. In connection with the form ation of the nem atic phase, we discuss the origin of the rst order transition and competition with other broken symmetry states.

PACS num bers: 71.10 H f, 71.27.+ a

I. IN TRODUCTION

Recently, there have been reports of experim ental evidence of inhom ogeneous and/or anisotropic quantum ground states in strongly correlated system s.^{1,2,3,4,5} The inhom ogeneous phase dubbed the stripe phase was observed in high tem perature cuprates via elastic neutron scattering experiments.⁶ Theoretical studies of the inhom ogeneous and anisotropic quantum ground states in connection with generic phases of a doped M ott insulator have also been carried out. 7,8 It was suggested that as quantum uctuation, induced by hole doping, increases, the Mott insulator turns into a smectic stripe phase, and a further increase of quantum uctuation will turn a sm ectic to a nem atic phase.^{7,8} The electronic sm ectic and nem atic phases are characterized by broken translational (in one direction) and rotational symmetries, in analogy with classical liquid crystals.9

The electronic nem atic phase which breaks the pointgroup symmetry on a square lattice was studied in the extended Hubbard model. The instability of Fermi liquid towards possible ordered phases including the nem atic | called the Pomeranchuk instability¹⁰ | were investigated, and it was shown that the nem atic phase is the leading instability within some range of the param eter space.^{11,12,13} W ithin the weak coupling theory, the e ective Ham iltonian of the quadrupole-quadrupole density interaction for the nem atic phase was also constructed, where the expectation value of the quadrupole density is the order parameter of the nem atic phase.¹⁴ The study of the nem atic phase and possible superconductivity in the continuum model within the weak coupling approach showed the non-Ferm i liquid behavior in the single particle scattering rate¹⁴ and an exotic superconducting pairing symmetry¹⁵ via the coupling to the collective modes. Possible probes of the nem atic phase were also discussed.^{16,17}

The nature of the quantum phase transition between the nem atic phase and isotropic Ferm i liquid as a function of chem ical potential, for a particular set of parameters (interaction strength F_2 and next nearest neighbor hopping t^0), was recently studied num erically.¹⁸ T his com putation showed that the transition is generically rst order. On the other hand, R ef. 19 found anisotropic non-Ferm iliquid behavior at the isotropic-nem atic quantum criticalpoint second order transition in the presence of a lattice. Therefore it is in portant to investigate whether the nature of isotropic-nem atic transition depends on the type of electron dispersion, the interaction strength, or the tem perature.

In this paper, we investigate the behavior of the free energy and density analytically, as a function of chem ical potential and interaction strength. We also extend the analysis to nite tem perature and quasi-2D electron dispersion. At zero tem perature, we show that the nem atic transition is rst order as a function of the interaction strength and chem ical potential for all typical 2D electronic dispersions since they possess van H ove singularities. The transition changes to a continuous one at a nite tem perature, but is not strongly a ected by sm all dispersion in the third direction.

We also nd that the transition takes place for arbitrarily sm all attractive interaction at the van H ove band lling. In the absence of interaction, at the van Hove lling, the Ferm i surface changes topology from electronto hole-like. This transition, rst studied by Lifshitz^{20,21}, causes singularities in therm odynam ic quantities such as com pressibility, due to van Hove singularities, but is not accompanied by any broken symmetry. This transition was recently revisited in Ref. 22 as an example of phase transition between di erent quantum orders which are not classi ed by broken symmetry. Our ndings show that the Lifshitz transition does not take place because the van Hove singularity is avoided due to a sudden change of the Ferm i surface topology. This has im plications for earlier studies of broken symmetry states, such as density waves. These studies^{11,13,23,24,25,26} were based on the existence of the van Hove singularity, which lead to a divergence of the relevant susceptibility indicating a transition to an ordered phase. Our results suggest that these ordered phases may be preem pted by the rst order transition into the new atic phase.

The paper is organized as follows. We describe the

e ective model H am iltonian for the nem atic in section II. The mean eld analysis at zero tem perature and nite tem perature is given in section III. A possible connection to other competing instabilities is discussed in section IV. W e also provide the sum mary of our notings in the last section, IV.

II. MODEL

A. Ham iltonian

Our choice of model H am iltonian is largely motivated by symmetry considerations and by the philosophy of the weak-coupling BCS theory. The interaction is chosen with foresight toward the mean-eld analysis and with inspiration from classical liquid crystal theory. In a liquid crystal, each rod-like molecule de nes a direction in space, and the order parameter for the nem atic phase is equally sensitive to their alignment as well as anti-alignment. It is a quadrupole (second order sym m etric traceless) tensor built from these directions. In two dimensions, it changes sign under a rotation by 90 and is invariant under a rotation by 180 . For an electron gas, we can construct a similar order parameter from the momenta of electrons, the quadrupole density $\hat{Q}_{ij} = \hat{p}_i \hat{p}_j \frac{1}{2} \hat{p}^2_{ij}$. The interaction between quadrupole densities (suitably quantized and discretized) is made attractive to favor the alignm ent or anti-alignm ent of electron m om enta, i.e. form ation of the nem atic phase.

The precise H am iltonian under consideration is written as

$$H = \begin{pmatrix} X & & & & \\ & & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & &$$

where "_k is the single-particle dispersion, $F_2(q)$ is the inter-electron interaction strength, and $\hat{Q}(q)$ is the the lattice analog of the quadrupole density tensor constructed in two dimensional square lattice from particle momenta given by

$$\hat{Q}(q) = \frac{1}{N} \sum_{k}^{N} c_{k+q}^{y} \frac{\cos k_{y}}{\sin k_{x}} \frac{\sin k_{x}}{\sin k_{y}} \frac{\sin k_{x}}{\cos k_{x}} \frac{\sin k_{y}}{\cos k_{x}} c_{k};$$
(2)

The dispersion is that of a next-nearest-neighbor tight binding model on a square lattice ${\tt "k}=2t(\cos k_x+\cos k_y)$ $4t^0\cos k_x\cos k_y$. While $F_2(q)$ is an arbitrary short ranged interaction, for example of the (two dimensional) Yukawa form ,

$$F_{2}(q) = \frac{F_{2}}{2} \frac{2^{2}}{(1 + {}^{2}q^{2})^{3=2}};$$
 (3)

W e shall only be interested in the strength of the interaction F_2 , which is assumed to be positive.

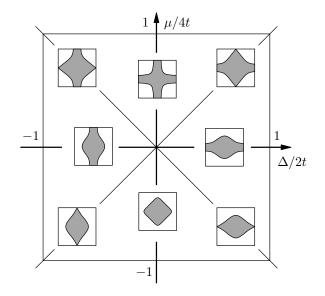

FIG.1: Shapes of the Ferm i surface (FS) for di erent values of and . Lines (=2)² = ² m ark the van Hove singularities in the DOS which correspond to the FS touching the boundary of the Brillouin zone.

III. MEAN-FIELD ANALYSIS

To decouple the quartic interaction in Eq. (1), we concentrate on the q = 0 interactions (which is equivalent to letting $F_2(q) ! \frac{1}{2}F_{2q;0}$ as ! 1 in Eq. (3)) and de ne two order parameters,

=
$$F_2 h \hat{Q}_{xx}$$
 (0) i and $^0 = F_2 h \hat{Q}_{xy}$ (0) i; (4)

where the expectation value $h_k^y c_k i$ is replaced by the Ferm i distribution n_F ("_k), and "_k is the the renormalized single-particle dispersion relation

$$U_{k} = 2t(\cos k_{x} + \cos k_{y}) \quad 4t^{0}\cos k_{x} \cos k_{y} + (\cos k_{x} \cos k_{y}) \quad {}^{0}\sin k_{x} \sin k_{y} : (5)$$

A nite t^0 does not qualitatively change the physics of the model. For simplicity, the value $t^0 = 0$ was used in the T = 0 calculations, but a nonzero t^0 was used at nite temperature.

A non-zero expectation value of \hat{Q}_{ij} indicates that the rotational (lattice point-group) symmetry has been broken and a preferred direction for electron momenta has been selected. In particular, a non-zero expectation value of \hat{Q}_{xy} indicates that this direction is not parallel to either of the crystal axes. The prole of both the interaction and the bare dispersion favor alignment along the crystal axes, as long as the coupling constants for diagonal \hat{Q}_{xx} and o -diagonal \hat{Q}_{xy} elements are the same, $F_2^{xx} = F_2^{xy}$. Hence we expect ⁰ to vanish. This observation has been con rm ed by num erical calculations.¹⁸

In general, unlike in the continuum model¹⁴ with full rotational symmetry, the coupling constants F_2^{xx} and

 F_2^{xy} can be dierent. In such cases, a nite ⁰ is possible. In fact broken symmetry states with oblique alignment, such as diagonal stripes, have been discussed in Ref. 27.

A. Free energy

The resulting mean-eld grand-canonical free energy density is given by

$$F(;) = \frac{1}{F_2} \frac{2}{2} + F_0(;); \qquad (6)$$

where F_0 is

$$F_{0}(;) = \frac{1}{2} d"D(") \ln(1 + e^{(")}); \quad (7)$$

with D (") being the density of states (DOS) of the singleparticle dispersion (5). Its exact expression is (see Appendix for details and de nitions)

D (") = N₀ Re
$$\frac{1}{1 (\frac{\pi}{4t})^2}$$
K 1 $\frac{2 (\frac{\pi}{2})^2}{(2t)^2 (\frac{\pi}{2})^2}$; (8)

where N₀ = 1=(2t²). For J'j > 4t, D (") vanishes. Note the logarithm ic van Hove (vH) singularities in the DOS at ("=2)² = ². These singularities occur when the constant energy contour (Ferm i surface) m eets the boundary of the rst B rillouin zone as shown in Fig.1. Due to these rem nants of the vH singularity of the non-interacting system, the free energy F (;) will exhibit non-analytic behavior at (=2)² = ². This behavior is to be contrasted with the free energy in the presence of density wave order parameters, where all singularities are smoothed. U ltim ately, persistence of non-analyticities in F (;) leads to the rst order isotropic-nem atic quantum phase transition.

B. Zero tem perature

First we analyze the free energy density in the lim it of zero tem perature ($\ ! \ 1$). In this lim it

$$F_0(;) = (E n);$$
 (9)

where E and n are the energy and particle density per unit cell.

The energy integral can be evaluated exactly, but the density integral cannot. The combined expression for the free energy (for ; $\frac{1}{2}$ < 2t, and neglecting term s independent of) is

$$F = \frac{1}{F_2} + 2N_0 - \frac{2}{2} + N_0 + \frac{2}{2} \ln \frac{+2}{4} + (1 + 1); \quad (10)$$

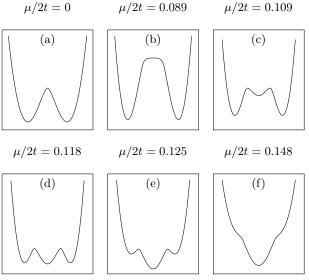

FIG.2: Plots of free energy as a function of for di erent values of the chemical potential ($F_2N_0 = 0.1$) centered at = 0; (b) = , (d) = $_{\rm c}$ (see text).

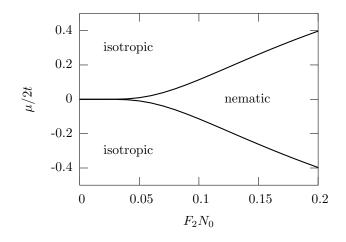

FIG. 3: Phase diagram in the F_2 parameter space. Solid curve, given by $_c$ (12), is the line of the rst order transition.

where for brevity all energy quantities are in units of 2t. Any results extracted from this expression are valid up to quadratic order in and . The details of the calculations are outlined in the Appendix.

The free energy for dierent chemical potentials is plotted as a function of in Fig.2. As the chemical potential decreases, the free energy develops local minima at nite

(the nem atic phase), which then become the global m inim a for j j < $_{\rm c}$. It is clear that the transition between isotropic and nem atic phases is rst order.

From Eq. (10), one can also show that = 0 is always an extremum of the free energy. However, no local minimum of the free energy can be located in the region

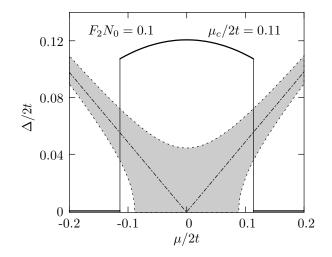

FIG. 4: Equilibrium value of the order parameter . The shaded region indicates negative curvature of the free energy. Lines $2 = (\frac{1}{2})^2$ are marked by dot-dashed lines.

$$j(\frac{1}{2})^2$$
 ² $j < (\frac{1}{2})^2$, where
=2t = 1:08e $\frac{1}{4F_2N_0}$; (11)

this is the lim it of m etastability of the isotropic phase (=0) which becomes unstable for $j j < \ldots$ Hence, must have a nite equilibrium value in this region (nem atic phase). The phase transition actually takes place slightly outside this region at $j j = \ldots$,

$$_{c}=2t=1:39e^{\frac{1}{4F_{2}N_{0}}}$$
: (12)

W e stress again that $_{\rm c}$ > , which indicates that the nem atic transition takes precedence over the Pom eranchuk instability (divergence of susceptibility). In Fig. 3, we show the line of the rst order phase transition in the parameter space of interaction strength, F₂, and chem icalpotential.

The nontrivial localm in im a are located at

$$=2t = 1:47e^{-\frac{1}{4F_2N_0}} - 1:36e^{\frac{1}{4F_2N_0}} - \frac{2}{2t}: \quad (13)$$

Eq.13 is valid for j j< c. The Fig. 4 shows the behavior of the order param eter. The order param eter jum p and the width of the nem atic window decrease exponentially as the coupling strength F_2 goes to 0. The unstable region j² $(\frac{1}{2})^2 j < (\frac{1}{2})^2$ is shaded in Fig. 4. A local minimum of the free energy can only be found outside this area, which explains the discontinuous character of the phase transition, since the equilibrium value of the order param eter must jum p to avoid it. The dot-dashed 2 , are where the change in topology of lines, $(\frac{1}{2})^2 =$ the Ferm i surface takes place, the Lifshitz transition. As shown in Fig. 4, these lines are embedded in the unstable region. Therefore, our results indicate that, in the presence of interaction, the Lifshitz transition is not realized due to the form ation of the nem atic phase.

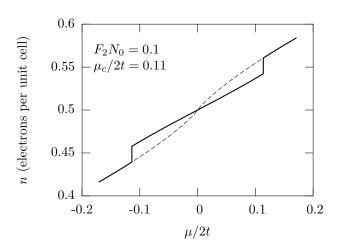

FIG. 5: The electron density per unit cell. The jump in the density is a signature of a rst order phase transition.

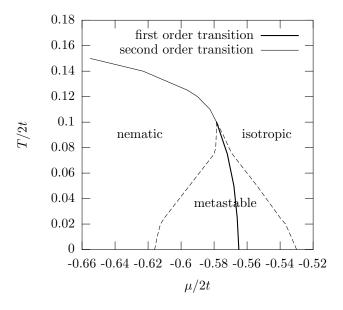

FIG. 6: The nite temperature phase diagram for the isotropic-nematic transition. The rst order transition persists at low temperatures. However, the metastable region gets smaller and smaller with increasing temperature. Finally, around T=2t=0.1, the phase transition becomes continuous.

The density as a function of is shown in Fig.5. Notice that the dotted line is the density in the absence of nem atic order. Its derivative at = 0 is singular, which signals the Lifshitz transition. However, once the nem atic order sets in, the density at half lling becomes sm ooth, but shows a discontinuity at c.

C. Finite tem perature

To investigate the robustness of the rst order isotropic-nem atic transition, we study the transition at nite temperature and with a nite inter-plane hopping tem t_z . These calculations are performed numerically using the same technique as in Ref. 18. The rst order transition is robust against a small $t_z = 0.1t$ tem, but changes to a second order one at a nite temperature.

The phase diagram for nite temperatures is shown in Fig. 6 for a xed $F_2N_0 = 0.11$ and a nite next nearest neighbor hopping t^0 ($t^0 = 0.4t$). The full width of the nem atic window is from =2t = 0.94 to 0.57.¹⁸ It is worth noting that the rst order transition does not alter qualitatively with a nite t^0 .

A negative (positive) t^0 shifts the window of the nem atic phase to the hole- (electron-) doped side. At low tem peratures the transition is still rst order surrounded by a metastable region (which indicates the presence of unstable local minim a). However, at about T=2t=0.1, the metastable region disappears and the transition becomes continuous.

The discontinuity in the isotropic-nem atic transition at zero tem perature can be traced to the presence of the lattice, which dictates the form of the dispersion relation and the presence of the van Hove singularity, and the sharpness of Ferm i distribution. W ith increasing tem perature, the therm al uctuation will sm ear the sharpness of the Ferm i distribution function, which results in a sm aller jump in the order parameter and nally in a continuous transition. This expectation is con rm ed by the num erics presented here.

IV. DISCUSSION AND SUMMARY

There has been a number of one-loop renorm alization group studies for the H ubbard m odel taking into account the Ferm i surface only at the saddle points, (;0) and (0;), namely the two patch m odel at van H ove lling. These studies showed that there are antiferrom agnetic and d-w ave pairing instabilities in H ubbard m odel.^{23,24,28} R ecently the two patch m odel was revisited, and truncation of the Ferm i surface near the saddle points was suggested.²⁵

On the other hand, the instability of the Ferm i liquid towards the formation of the nematic phase Pomeranchuk instability | with other competing orders were also recently investigated using di erent methods in the extended Hubbard model^{11,12,13,26} and the t-J model²⁹ In Ref. 11, the authors noticed that the nematic instability is driven by the attractive (repulsive) interaction between electrons in the same (di erent) patches via forward scatterings in the Hubbard model. This nding is consistent with our electrons near (;0) and (;0), and a repulsive one between (;0) and (0;). While

the understanding of the e ective interaction for the nematic phase from the microscopic Hamiltonian is still missing, it suggests that the e ective nematic interaction is hidden in the extended Hubbard model.

O ur discovery of a strong tendency tow and the nem atic phase near van Hove lling suggests that the two patch m odel should be revisited. Since the nem atic order occurs for extrem ely sm all interaction near van Hove lling, the existence of saddle points itself should be addressed. Since the Ferm i surface topology \suddenly" changes from closed to open as indicated in our result, we speculate that the instability tow ands com peting orders such as antiferrom agnetic and charge density wave (which are sensitive to the topology of the Ferm i surface and enhanced by van Hove singularity) would be suppressed by the form ation of the nem atic phase.

In sum mary, we have investigated a model H am iltonian exhibiting the nem atic phase. At zero temperature the isotropic-nem atic transition takes place for arbitrarily small coupling at van H ove band lling. Away from the van H ove lling, a nite m inimum interaction is required to stabilize the nem atic phase. The phase transition is rst order as a function of interaction strength (chem ical potential) for a xed chem ical potential (interaction strength) as shown in F ig.3. The strong tendency tow ard the nem atic phase for an arbitrary sm all interaction at van H ove lling suggests that the Lifshitz transition is suppressed in the presence of interactions. At a nite temperature the transition becomes second order, while it remains rst order for a quasi-2D dispersion.

This expression is a leading order expansion in $(\frac{1}{2})$. Here, for brevity, and are in units of 2t.

Expanding the energy density to the same order, the combined free energy (neglecting terms independent of) is given in Eq. (10). Equating to zero the rst derivative of the free energy with respect to gives an equation for its local extrem a. Nontrivial m inim a are easily found at = 0. In Eq. (13) location of these m inim a is given to quadratic order in . Using this expression we can not the chemical potential $_{\rm c}$ (Eq. (12)) at which they become global m inim a. Equating to zero the second derivative of the free energy with respect to , we not the chemical potential (Eq. (11)) at which the extrem um at = 0 changes from a local m inim um to a maxim um.
