Abstract. We study by M onte C arlo simulations the in uence of bond dilution on the three-dimensional Ising model. This paradigmatic model in its pure version displays a second-order phase transition with a positive speci c heat critical exponent . A coording to the H arris criterion disorder should hence lead to a new xed point characterized by new critical exponents. We have determ ined the phase diagram of the diluted model, between the pure model limit and the percolation threshold. For the estimation of critical exponents, we have st performed a nite-size scaling study, where we concentrated on three di erent dilutions. We emphasize in this work the great in uence of the cross-over phenom ena between the pure, disorder and percolation xed points which lead to e ective critical exponents dependent on the concentration. In a second set of simulations, the tem perature behaviour of physical quantities has been studied in order to characterize the disorder xed point more accurately. In particular this allowed us to estim ate ratios of som e critical am plitudes. In accord with previous observations for other m odels this provides stronger evidence for the existence of the disorder xed point since the amplitude ratios are more sensitive to the universality class than the critical exponents. M oreover, the question of non-self-averaging at the disorder xed point is investigated and compared with recent results for the bond-diluted q = 4Potts model. Overall our num erical results provide evidence that, as expected on theoretical grounds, the critical behaviour of the bond-diluted m odel is governed by the same universality class as the site-diluted m odel

# 1 Introduction

The in uence of quenched, random disorder on phase transitions has been the subject of num erous experim ental and theoretical investigations since more than 20 years [1]. They concern both rst- and second-order phase transitions, especially in two dimensions. The qualitative in uence of quenched, short-range correlated [2] random disorder at second-order phase transitions is well understood since Harris [3] proposed a relevance criterion based on the know ledge of the speci c heat critical exponent of the pure model: when is positive, under a coarse graining, the disordered system should reach a so-called niterandom ness disorder xed point characterized by altered critical exponents, whereas if is negative, the universality class of the pure system will persist. In particular

the two-dimensional (2D) Ising model has attracted great interest in the past years because of its interm ediate situation ( = 0) which implies a marginal in uence of disorder [4]. From an experimental point of view, a con mation of the Harris criterion was reported in a LEED investigation of a 2D order-disorder transition [5,6]. In the case of a rst-order phase transition in the pure model, disorder is expected to soften the transition and, under som e circum stances, m ay even induce a second-order transition [7]. For 2D systems, the latter scenario has been proved by A izenm an and W ehr on rigorous theoretical grounds [8, 9]. To test these theoretical predictions also the Potts model [10] has been intensively studied in 2D [11] since it displays the two di erent regim es: a second-order phase transition when the number of states per spin q 4 and a rst-order one when q > 4. These results were obtained by di erent techniques including M onte C arlo sim ulations, transfer matrix calculations, eld-theoretic perturbation

<sup>&</sup>lt;sup>a</sup> Author for correspondence (pierre.berche@univ-rouen.fr).

theory, and high-tem perature series expansions [12,13, 14,15,16,17,18,19,20,21,22].

In three dim ensions (3D), the disordered Potts m odel has of course been studied only later: the case q = 3, corresponding to a very weak rst-order transition for the pure m odel [23], has been investigated num erically by Ballesteros et al. [24] for site dilution, and the case q = 4, exhibiting in the pure system a strong rst-order transition [25], has been studied very recently by us [26,27, 28,29,30] for bond dilution via large-scale M onte Carlo simulations. Only the 3D Ising model with site dilution has also been extensively studied using M onte C arlo sim ulations [31,32,33,34,35,36,37,38,39,40,41,42,43,44,45], or eld theoretic renorm alization group approaches [46, 47,48,49,50,51,52,53,54,55]. The diluted model can be treated in the low-dilution regime (concentration of magnetic bonds, p, close to 1) by analytical perturbative renormalization group methods [56,57,58,59,60] where a new

xed point independent of the dilution has been found, but for stronger disorder only M onte C arlo simulations rem ain valid.

The rst num erical studies [32,33,34] suggested a continuous variation of the critical exponents along the critical line but after the works [35,36,37,38,39] it became clear that the concentration dependent critical exponents found in M onte C arlo simulations are e ective ones, characterizing the approach to the asymptotic regime. The critical exponents and associated with the magnetisation and susceptibility, respectively, were shown by Heuer [38] to be concentration dependent in the region 0.5 p < 1. The conclusion of Heuer was: while a crossover between the pure and weakly random xed points accounts for the behaviour of system s above p' 0:8, in m ore strongly disordered systems a more re ned analysis is needed. We should mention here that the meaning of p is not exactly the same in the papers mentioned above which refer to site dilution and in our present study in which we are interested in bond dilution. That is why the num erical values of p given before for the di erent regim es cannot directly be taken over to the bond-dilution case.

A nother in portant question has been investigated by W isem an and Dom any [43,44]: it concerns the question of the possible lack of self-averaging which can happen in disordered systems. For the 3D site-diluted Ising model close to criticality they explicitly showed that physical quantities such as the magnetisation or susceptibility are indeed not self-averaging. A though simulations [44] revealed that disorder realized in a canonicalm anner ( xing the fraction p of m agnetic sites) leads to di erent results than those obtained from disorder realized in a grandcanonical ensemble (assigning to each site a magnetic mom ent with probability p), the renorm alization-group approach of Ref. [61] shows that the canonical constraint is irrelevant, even near the random xed point, suggesting that the observed di erences are a nite-size e ect. The studies of R ef. [42] were based on the crucial observation that it is in portant to take into account the leading corrections-to-scaling term in the in nite-volum e extrapolation of the M onte C arlo data. Thus, the m ain problem

encountered in these studies of the disordered Ising m odel was the question of m easuring e ective or asym ptotic exponents. A lthough the change of universality class should happen theoretically for arbitrarily weak disorder, the new critical exponents appear only in a sm all tem perature region around the critical point, whose size is controlled by the concentration of the non-m agnetic com pound. Equivalently, in nite-size scaling studies very large lattices are required to observe the asym ptotic behaviour. In fact, the asym ptotic regions cannot always be reached practically and one therefore often m easures only e ective exponents.

A nother crucial problem of the new critical (e ective or asym ptotic) exponents obtained in these studies is that the ratios = and = occuring generically in nite-size scaling analyses are alm ost identical for the disordered and pure m odels. For the pure 3D Ising m odel, accurate values are [62]:

$$= 0:6304(13); = 0:0335(25);$$

which gives:

$$= = 0:517(3); = = 2 = 1:966(3);$$

and = 0:1103(1) > 0, i.e., disorder should be relevant according to the Harris criterion.

For the site-diluted model, the asymptotic exponents given by Ballesteros et al. [42] are:

$$= = 0:519(3); = = 1:963(5); = 0:6837(53):$$

Thus, nite-size scaling techniques will only be able to di erentiate between the values of at the two xed points, but will not be very e cient for distinguishing ratios of critical exponents. E ven if and them selves happen to be quite di erent, the ratios = and = are very cbse. That is the reason why a study of the tem perature behaviour of the m agnetisation and susceptibility will be very helpful for an independent determ ination of the exponents and .

Contrary to previous studies of the disordered Ising model which were concerned with site dilution, we have chosen to model the disorder by bond dilution in order to compare these two kinds of disorder and to verify that they indeed lead to the same set of new critical exponents, as expected theoretically by universality argum ents. In the following we shall thus consider the bond-diluted Ising model in 3D whose Ham iltonian with uncorrelated quenched random interactions can be written (in a Potts m odel norm alization) as

$$H = \mathop{K}_{(i;j)} K_{ij}, \qquad (1)$$

where the spins take the values  $_{i} = 1$  and the sum goes over all nearest-neighbour pairs (i; j). The coupling strengths are allowed to take (grand-canonically) two different values K  $_{ij} = K$   $J=k_{\rm B}$  T and 0 with probabilities

p and 1 p, respectively,

$$P[K_{ij}] = \begin{array}{c} Y \\ P[K_{ij}] = \begin{array}{c} P(K_{ij}) \\ Y \\ = \begin{array}{c} (i_{j}; j) \\ Y \\ (i_{j}; j) \end{array} (K_{ij} K) + (1 p) (K_{ij})]; \quad (2) \end{array}$$

c = 1 p being the concentration of m issing bonds, which play the role of the non-m agnetic in purities.

The plan of the rest of the paper is as follows: in section 2, we present the phase diagram of the bond-diluted Ising model. Then, in section 3, we discuss the averaging procedure and investigate the question of possible nonself-averaging of physical quantities. The section 4 is devoted to the critical behaviour of the disordered model. In the rst part we present our nite-size scaling study of three particular concentrations p, and the second part deals with the tem perature scaling for the same three dilutions. Finally, section 5 contains our conclusions.

### 2 Phase diagram

In order to determ ine the phase diagram and the critical properties at a few selected dilutions we perform ed in this study large-scale M onte C arlo simulations on sim ple cubic lattices with  $V = L^3$  spins (up to L = 96) and periodic boundary conditions in the three space directions, using the Swendsen-W ang cluster algorithm [63] for updating the spins. The histogram reweighting technique [64,65] was employed to extend the results over a range of K around the simulation point. All physical quantities are averaged over 2000 { 5000 disorder realisations, indicated by a bar (e.g., m for the magnetisation). Standard de nitions were used, e.g., for a given disorder realisation, the magnetisation is de ned according to m = hj ji where h:::i stands for the therm al av-=  $(N_{\#} N_{\#}) = (N_{\#} + N_{\#})$ . The susceptibilerage and ity follows from the uctuation-dissipation relation,  $K V (h^{2}i h^{2}j^{2})$ . Here, one should notice that a de nition which is usually used in the disordered phase in M onte Carlo simulations, and which seems to be more stable, = KVh<sup>2</sup>i, should be avoided in quenched disordered system s.Simulating at a given tem perature above the crit-

icalpoint, one may indeed encounter samples which have higher e ective transition temperatures, and which thus have non-zero hj ji.

The phase diagram was obtained by locating the maxim a of the average susceptibility  $_{\rm L}$  (a diverging quantity in the therm odynam ic lim it) for increasing lattice sizes L as a function of the coupling strength K , with the dilution parameter p varying from the neighbourhood of the pure m odel (p = 0.95) to the very diluted m odel (p = 0.36), see F ig. 1.

Below the percolation threshold  $p_c$  ' 0.2488 [66], one does not expect any nite-temperature phase transition since without any percolating cluster in the system longrange order is impossible. The approximate phase diagram [67] as obtained from the susceptibility maxima for the largest lattice size (L = 20) is shown in Fig.2.For comparison, we have drawn a simple mean-eld (MF) estimate of the transition point

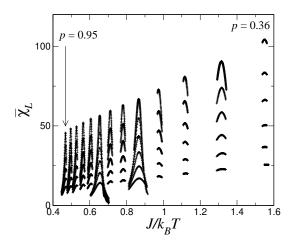

$$K_{c}^{MF}(p) = pK_{c}(1);$$
 (3)

where K  $_{\rm c}$  (1) = 0:443 308 8 (6) [68] is the accurately known transition point of the purem odel (in the Pottsm odelnormalization), and the single-bond e ective-medium (EM) approximation [69]

$$K_{c}^{EM}(p) = \ln \frac{(1 p_{c})e^{K_{c}(1)} (1 p)}{p p_{c}};$$
 (4)

which gives a very good agreement with the simulated transition line over the full dilution range. We have om itted results from recent high-temperature series expansions [70] since, on the scale of Fig. 2, they would just fall on top of the M onte C arb data.

To get an accurate determ ination of K  $_{\rm c}$  (L), we used the histogram rew eighting technique with at least  $N_{M,C,S}$  = 2500 M onte C arlo sweeps and between 2000 and 5000 sam ples of disorder. The num ber of Monte Carlo sweeps is justi ed by the increasing behaviour of the energy autocorrelation time \_ as a function of p and L.For each size, we perform ed at least 250 independent m easurem ents of the physical quantities (N  $_{\rm M \, C \, S}$  > 250  $_{\rm e}$  ). For a second-order phase transition, the autocorrelation time is expected to behave as L<sup>z</sup> at the critical point where z is the dynam ical critical exponent. For the disordered Ising model, we obtained from the least-squares ts shown in Fig. 3 the values of z com piled in Table 1.W e see that the critical slow ing-down weakens for the disordered model and that z becomes e ectively smaller when the concentration of m agnetic bonds p decreases. The observed variation of the dynam ical exponent z is probably due to the in uence of the di erent xed points encountered (pure, disorder and

F ig. 1. Variation of the average magnetic susceptibility  $_{\rm L}$  versus the coupling strength K =  $J{=}k_{\rm B}\,T$  for several concentrations p = 0:95;0:90;:::;0:36 and L = 10;12;14;16;18;20. For each value of p and each lattice size, the curves are obtained by standard histogram reweighting of the simulation data at one value of K .

percolation), as will be discussed below in more detail for the static critical exponents.

The largest autocorrelation time observed for the disordered m odel was around  $_{\rm e}$  9 for p = 0:7 and L = 96.

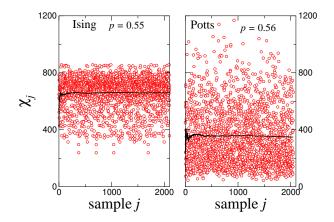

F ig. 3. Energy autocorrelation time  $_{e}$  versus the size L of the system on a log-log scale. The pure case corresponds to p = 1. The straight lines show ts of the form  $_{e} / L^{z}$ , yielding the elective dynam ical critical exponents z compiled in Table 1.

#### 3 N on-self-averaging

In order to achieve accurate results for quenched, disordered systems in numerical simulations it is important to obtain an estimate of the required number of disorder realisations. This is particularly important in the vicinity of a critical point where the correlation length diverges. As a consequence the (disorder) distributions of physical observables typically do not become a sharper with increasing system size at a nite-random ness disorder xed point.

Table 1. E ective dynamical critical exponent z as obtained from linear tsoflog  $_{\rm e}$  vslogL. The simulations are performed at the pseudo-critical couplings K  $_{\rm c}$ (L) (cf. Table 2 and Fig. 10 below). Here we give in the second line only the simulation coupling K for the largest lattice size L = 96.

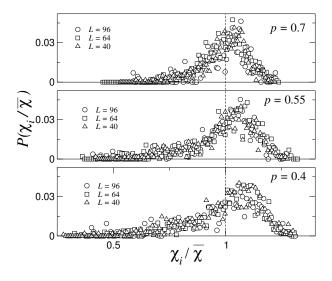

р	1	0 <b>:</b> 7	0:55	0:4
Κ	0:4433	0 <b>:</b> 6535	0:8649	1:3136
Z	0:59	0:41	0:38	0:27

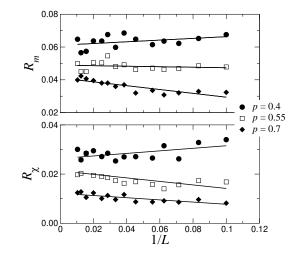

F ig. 4.D isorder distribution of the susceptibility for the Ising and q = 4 Pottsm odelsw ith a concentration ofm agnetic bonds of 0:55 and 0:56, respectively, and a lattice of size L = 64. The simulations are m ade at K = 0:8655 K<sub>c</sub>(L) for the Ising m odel and K = 1:12945 K<sub>c</sub>(L) for the Pottsm odel. In the latter case, the concentration p = 0.56 belongs to the second-order regime [26]. The running average over the sam ples j is shown by the thick solid line.

R ather their relative widths stay constant, a phenom enon called non-self-averaging. In order to investigate the disorder averages, we produced N  $_{\rm s}$  di erent sam ples and com puted the corresponding susceptibilities 1, 1 j N<sub>s</sub>. In Fig. 4 we compare the distributions for the Ising and q = 4 Pottsm odels (in the second-order regime [26]). The gure shows that the dispersion of the values of is less im portant for the disordered Ising m odelw here rare events correspond to low values of . This im plies that their contribution to the average is not so crucial as for the Potts model where a long rare-event tail is found on the largeside. This is the reason why for the Ising model the uctuations in the average value disappear after a few hundred realisations and why the disorder averaging procedure is more e cient than for the Potts model.

To test if self-averaging is valid or not for the disordered model [43,44], we investigated the variation of the shape of the probability distributions of the susceptibility when the size is increasing. Dividing the interval ( $_{max}$   $_{min}$ ) into 100 bins, we computed the probability for each value of to belong to the bin i (1 i 100). The resulting probability distribution P ( $_{i}$ = ) (norm alized to unity) is drawn in Fig. 5 versus the ratio of the average susceptibility  $_{\rm i}$  of the bin i and the global average susceptibility .

F ig. 6. Normalized squared width of the magnetisation and susceptibility distributions versus the inverse of the lattice size for the three concentrations p = 0.4;0.55, and 0.7 at the elective critical coupling K  $_{\rm c}$  (L). The straight lines are linear to used as quides to the eye.

F ig. 5. P robability distribution of the susceptibility versus the ratio of the average value of the susceptibility of bin i and the global average susceptibility for the bond-diluted Ising m odel (p = 0.7, 0.55, and 0.4) for L = 40;64, and 96. The simulations are performed at K  $_{\rm c}$  (L). The vertical dashed line indicates the average susceptibility  $_{\rm i} = 1$ .

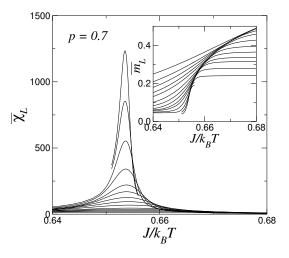

For the three studied dilutions, the shape of the curve does not becom e sharper with increasing size and the general shape remains remarkably independent of the dilution, a phenom enon which strongly contrasts with the situation encountered in the case of the q = 4 P ottsm odel [26]. N on self-averaging can be quantitatively checked by evaluating the norm alized squared width R (L) = V (L) =  $\overline{(L)}^2$ , where V is the variance of the susceptibility distribution:  $V(L) = {}^{2}(L)$ (L)<sup>-</sup>. The sam e quantity is also evaluated for the magnetisation:  $R_m$  (L) =  $V_m$  (L)= $\overline{m}$  (L)<sup>2</sup>. These ratios are shown versus the inverse lattice size for the three studied concentrations of the disordered Ising m odel in Fig. 6. The fact that  $R_m$  and R approach a constant when L increases as predicted by A harony and H arris [71] is the signature of a non-self-averaging system, in agreem ent with the results of W isem an and D om any [43, 44] for the site-diluted 3D Ising m odel. In fact, our num erical values of  $R_m$  are close to the estimate  $R_m = 0.055$  (2) for site dilution reported in Ref. [44]: when the system size goes to in nity, our data are compatible with a convergence tow ards  $R_m = 0.05(1)$ , where the error estimate re ects the uncertainty in the remaining nite-size corrections which appear to be more pronounced than for site dilution. On the other hand, our limiting value for R seems at rst sight to be completely o from the estimate R •= 0:156(4) given in Ref. [44]. Upon closer inspection this discrepancy can be traced back to di erent de nitions of the susceptibility.W hile W isem an and Dom any worked with the  $\high-tem$  perature" expression  $^{0} = K V h^{2} i$ ,

we used the connected correlator =  $K V (h^2 i h j j l^2)$ , valid in both the low - and high-tem perature phase. Another di erence is that they evaluated <sup>0</sup> at the in nitevolum e critical coupling K $_{c}^{1}$  while we follow ed the pseudotransition points K  $_{m ax}$  (L) de ned from the location of the maxima (see below). In fact, when we evaluate R 🜼 (i.e., without subtraction), we nd for p = 0.7 and the largest sizes (where K  $_{\rm m\,ax}$  (L)  $\,$  K  $_{\rm c}^{1}$  ) about 10 tim es larger values than shown in Fig. 6:  $R_{\circ} = 0:1635, 0:1766$ , and 0:1630for L = 64, 80, and 96. This is in accord with a remark in Ref. [44] who noticed also for site dilution that R is sm aller by a factor of 7 10, which would lead to a crass violation of the leading-order prediction in = 4 d for the  $\tau = 1 = 4$  [71], while working with they obtained a much closer ratio of  $R_m = R_0 = 0.35(2)$ . In our p = 0.7 case we get, with  $R_m = 0.0407, 0.0423$ , and  $R_m = 0.0399$  for L = 64, 80, and 96, estimates of  $R_{m}$  =R  $_{\circ}$  = 0.2489, 0.2395, and 0.2448, in perhaps surprisingly good agreem ent with the renorm alization group prediction of 1/4.0 f course, given the large corrections seen otherwise, this agreem ent may be accidental, but it is also conceivable that the corrections do indeed partially cancel in the \ratio of ratios".

Still, the apparent non-universality of R and to a weaker extent also of  $R_m$  (the ratios seem to depend on the in purity concentration) remains puzzling. It may be attributed to crossover e ects between the pure, disorder and percolation xed points which may be more sensitive for bond dilution than for site dilution. Another possible reason for quantitative discrepancies might be the fact that  $R_m$  and R were estimated in our study at the tem – perature corresponding to the maximum of the average susceptibility for the corresponding lattice size, and not at the critical point of the in nite system. This may lead to di erent scaling lim its for pure systems in the vicinity

Table 2. Values of the simulation points  $K = J = k_{\rm B} \, T$  (extrem ely close to the susceptibility maxim a) for the three mainly studied dilutions.

of  ${\rm T_c}),$  albeit causing presum ably only rather sm all deviations.

## 4 Critical behaviour

In order to study the critical behaviour of the bond-diluted Ising m odel, we have concentrated on the three particular concentrations p = 0.7, 0.55, and 0.4, for which the simulated lattice sizes go up to L = 96. For interested readers, the values of the simulation temperatures are reported in Table 2.

In Fig. 7 we show results of typical runs for the magnetisation (in the insert) and the susceptibility for p = 0.7

at a particular tem perature (or coupling) very close to the size-dependent critical point using the histogram rew eighting technique. From the scaling of the location and height of the peaks with lattice size of this and sim ilar quantities we then extracted the critical exponents of the system .

#### 4.1 Finite-Size Scaling Study

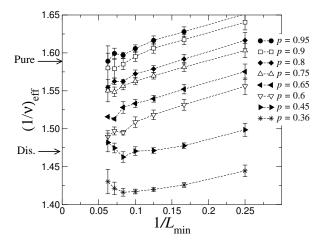

#### 4.1.1 Correlation length exponent

As mentioned in the introduction, the vicinity of the exponent ratios = and = for the pure and disordered universality classes does not allow, by the use of standard nite-size scaling (FSS) techniques, to discriminate between the two xed points from the behaviour of the magnetisation and the susceptibility, respectively. Only the critical exponent , which can be evaluated from the asym ptotic FSS behaviour of the derivative of the magnetisation versus tem perature,

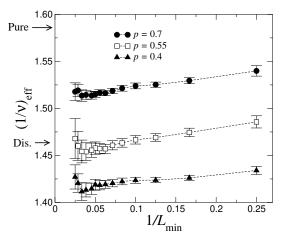

$$d \ln m = dK \qquad a_{d \ln m} L^{1=}; \qquad (5)$$

will be useful with this technique. But even for , one is trying to resolve an expected shift from the pure model's value by less than 10%. Taking the data evaluated at  $K_{max}$  and assuming the leading power-law behaviour (5), we have extracted by (linear) two-param eter least-squares ts over successively smaller ranges Lmin  $L_{max}$  the size-dependent e ective exponent (1= ) $_{\rm e}$  . Using the rst set of data for lattice sizes  $L = 4;6;8; \dots; 20 = L_{max}$ , the resulting exponents are plotted in a broad range of concentrations p against  $1=L_{m in}$  in Fig. 8 ( $L_{m in}$  is the sm allest lattice size used in the ts). We see that in the regime of low dilution (p close to 1), the system is clearly in uenced by the pure xed point. On the other hand, when the bond concentration is small, the vicinity of the percolation xed point induces a decrease of 1= below its expected disordered value. Indeed, the percolation xed point is characterized by 1= 1:12 [66].

As is demonstrated in Fig. 9, the same analysis for the three mainly studied dilutions with considerably larger lattice sizes going up to  $L = L_{max} = 96$  con m s the observation of the great in uence of both the pure and percolation xed points. The left-most data points in Fig. 9 with  $L_{m in} = 40$  follow from two-parameter least-squares ts of (d  $\ln m$  =dK )\_{K\_{max}} for our ve largest lattice sizes L = 40;50;64;80, and 96. Since this leaves only three independent degrees of freedom, moving further into the asymptotic large-L regime would be meaningless with the data available to us. The variation of  $(1 = )_{e}$  with  $L_{min}$ clearly indicates deviations of the data from the asymptotic ansatz (5), rooted in con uent corrections and crossoverterm sorboth. A swill be discussed in more detail below, we found it in possible, however, to resolve these corrections within a non-linear four-param eter ansatz. Still, som e rough estim ates of the critical exponent can be read o from Fig. 9, which are collected in Table 3.0 bviously, it would be very di cult to extract more precise values from this analysis. At a qualitative level, how ever, Fig. 9 clearly indicates that the dilution for which

F ig. 8. E ective exponents  $(1 = )_e$  as obtained from powerlaw ts in the range  $L_{m in}$   $L_{m ax} = 20$  as a function of  $1 = L_{m in}$ for p = 0.95; 0.9; 0.8; 0.75; 0.65; 0.6; 0.45, and 0.36. The error bars correspond to the standard deviations of the ts. The arrows indicate the values 1 = for the pure model [62] and the size-diluted one [42].

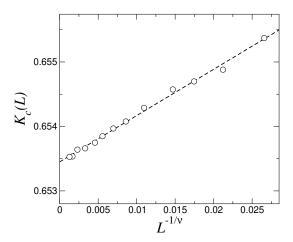

F ig. 9. E ective exponents (1= )<sub>e</sub> as obtained similar to F ig.8 from the behaviour of d hm =dK as a function of 1= $L_{m in}$  for p = 0:7, 0:55, and 0:4. Here the upper limit of the trange is  $L_{m ax} = 96$ .

the cross-over in uence will be the least is around p = 0.55 which suggests that the scaling corrections should be rather sm all for this speci c dilution.

#### 4.1.2 Critical couplings

The peak locations of the average susceptibility determ ine with a good accuracy the size-dependent (pseudo-) critical couplings K  $_{\rm c}$ (L), and from an in nite-size extrapolation, K  $_{\rm c}$ (L) = K  $_{\rm c}^{1}$  +  $a_{\rm K}$  L $^{1=}$ , the critical coupling in the therm odynam ic limit can be estimated. Inserting the just determ ined estimate of , the linear t shown in Fig.10 for p = 0:7 yields:

$$K_{c}^{1} = 0:6534(1):$$
 (6)

F ig. 10. Size-dependent critical coupling K  $_{\circ}$  (L) versus L <sup>1=</sup> for the bond-diluted Ising m odel with p = 0:7, using our estimate of = 0:66(1).

The same procedure gives for p = 0.55 and p = 0.4 the critical couplings K  $_{c}^{1} = 0.8645$  (2) and K  $_{c}^{1} = 1.3129$  (3), respectively.

#### 4.1.3 Susceptibility and magnetisation exponents

As already m entioned, the average m agnetisation m and susceptibility are expected to scale at the size-dependent critical coupling K  $_{\rm c}$  (L) with the lattice size as:

$$m_{K_{max}} a_m L = ; m_{ax} a L = ; (7)$$

where  $a_m$  and a are non-universalam plitudes.From least-squares ts to our extensive M onte C arlo data, we com – puted the e ective size-dependent ratios of the critical exponents ( = ), and ( = ), which are plotted in Fig.11 against  $1=L_m$  in for p = 0.7; 0:55, and 0:4, where  $L_m$  in is again the sm allest lattice size used in the ts.

Concerning them agnetisation, the e ective ratios clearly converge, when the size increases, towards 0:515(5) for the three dilutions in agreem ent with the expected values of the pure and site-diluted models. For the susceptibility, on the other hand, the behaviour of  $(=)_{e}$  is more di erentiated depending on the concentration p: the cases p = 0.7 and 0:55 are compatible with 1:965(10) if we take into account the error bars, very close to the pure and site-diluted model values, but the case p = 0.4 displays a (=) exponent a little bit larger. This discrepancy is probably due to the in uence of the percolation xed point whose = ratio is close to 2.05, according to the sam e scenario as for the exponent 1= . The critical exponents from the FSS study are summarized in Table 3 for the three studied dilutions, in good agreem ent with the hyperscaling relation d = 2 = + = .

Following the work of Ballesteros et al. [42] which em – phasized the great in uence of corrections-to-scaling to get an accurate determ ination of the critical exponents in the site-diluted Ising model, we tried to estimate them in the bond-diluted version as well. If we consider an irrelevant

the three dilutions.

р	0:7	0:55	0:4
1=	1:52(2)	1:46(2)	1:42(2)
	0 <b>:</b> 660 (10)	0 <b>:</b> 685(10)	0 <b>:</b> 705 (10)
=	0:515(5)	0:513(5)	0:510(5)
=	1 <b>:</b> 965 (10)	1 <b>:</b> 977 (10)	2:000(10)
2 = + =	2 <b>:</b> 995 (20)	3:003(20)	3:020 (20)

scaling eld g with scaling dimension  $y_{g} =$ ! < 0, thescaling expression of, e.g., the susceptibility is:

$$(L^{1};t;g) = L^{=} f (Lt;L^{!}g):$$
 (8)

Att = 0, around the xed point value q = 0, this leads to the standard expression a L = [1+b L !+O (L 2!)]. We hence tried to t the susceptibility data using the ansatz:

$$m_{ax}(L) = a L^{=} (1 + b L^{!})$$
: (9)

W e system at ically varied the exponent ratio = and the corrections-to-scaling exponent ! and determ ined them inin um of  $^2$ =d.o.f by performing linear ts in the range L 96 to x the amplitudes a and b. The result-18 ing <sup>2</sup>-landscape for p = 0.7 is shown in Fig. 12, where the base plane was restricted to the range 1:8 22 and 0 ! 4. The absolute minimum was found at = = 1:952; ! = 2:24, and a second, less pronounced minimum at = 2:112; ! = 0:01. The results for the magnetisation respectively its logaritm ic derivative and the other dilutions p = 0.55 and 0.4 look qualitatively sim ilar.

The gure may again be interpreted in favor of a com petition between the two xed points: the rst one is char-

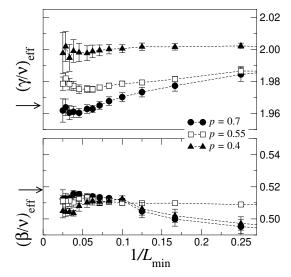

Fig. 11. E ective ratios ( = ), and ( = ), as a function of  $1=L_{m in}$  for p = 0.7, 0.55, and 0.4. The error bars correspond to the standard deviations of the power-law ts. The arrows indicate roughly the expected values for both the pure and disordered m odel.

Table 3. Critical exponents deduced from the FSS study of acterized by a valley in the !-direction, with an absolute minimum for a large value of !, i.e., sm all corrections toscaling since these corrections scale as L<sup>!</sup>. Then, this xed point should be the disordered one and the second the percolation xed point for which = ' 2:05 and = ' 0:48 [66]. But the accurate determ ination of the corrections-to-scaling exponent ! is very di cult because it strongly depends on the quantity considered ( max,  $m_{K_{max}}$  or (d lnm =dK )<sub>K\_max</sub>) and on the sizes included in the ts. Indeed, the valley in the ! direction does not display any deep minimum and the absolute minimum observed does not seem to be relevant concerning the value of ! . W e are thus not able to extract a num erical value of the corrections-to-scaling exponent, in contrast to previous claim s that ! 0:4 [42,48,49].

#### 4.2 Tem perature Scaling

The tem perature behaviour of the susceptibility and m agnetisation should allow to avoid the previous di culties generated by the vicinity of the ratios of the critical exponents. The critical exponents are indeed the following: pure Ising model: = 0.3258(14), = 1.2396(13) [62], site-diluted model: = 0.3546(28), = 1.342(10) [42].

As a function of the reduced tem perature  $t = (K_{c}, K)$ (t < 0 in the low -tem perature (LT) phase and t > 0 in thehigh-tem perature (HT) phase) and the system size L, the m agnetisation and the susceptibility are expected to scale as:

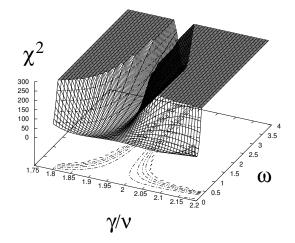

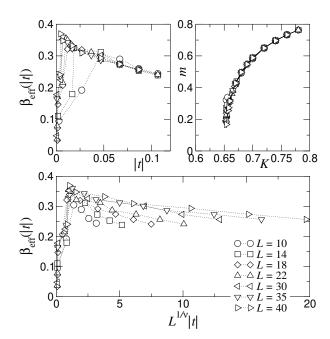

Fig. 12. Plot of the <sup>2</sup>-landscape deduced from linear ts of  $m_{ax}(L) = a L^{=} (1 + b L^{!})$  in the range 18 L 96 for the bond-diluted Ising model with concentration p = 0.7, exhibiting an absolute minimum at = 1:952; ! = 2:24and a secondary minimum at = 2:112; ! = 0:01. The exponents are xed parameters and the amplitudes are free. The cuto at  $^2$  = 300 has been introduced in order to improve the clarity of the gure.

F ig. 13.Variation of the tem perature dependent e ective critical exponent  $_{\rm e}$  (j;) = d ln m =d ln j; (in the low-tem perature phase) as a function of the reduced tem perature j; (top) and L<sup>1=</sup> j; (bottom) for the bond-diluted Ising m odel with p = 0:7 and several lattice sizes L. The data points are directly obtained from M onte C arlo data (no histogram reweighting). The m agnetisation vs. the coupling strength K = J=k<sub>B</sub> T in the ordered phase K > K  $_{\rm c}^{\rm L}$  is shown in the upper part.

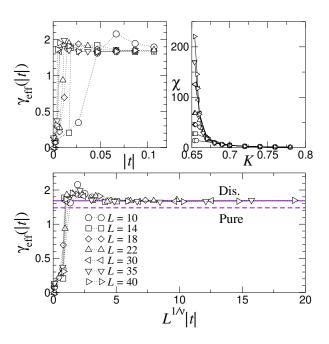

where f and g are scaling functions of the variable  $x = L^{1=}$  j and the subscript stands for the HT/LT phases. Then we can de ne tem perature dependent e ective critical exponents

$$e (tj) = d \ln m = d \ln tj; \qquad (12)$$

$$e^{(t)} = d\ln = d\ln t; \quad (13)$$

which should converge towards the asymptotic critical exponents and when L ! 1 and jj! 0. The results for p = 0.7 are shown in Figs. 13 and 14.

The e ective exponents e (1) evolve as a function of tjbetween a maximum value and 0 in the two tjdirections: when jj is large (K far from K<sub>c</sub>), the system is outside the critical region and the description with the critical exponents is no more valid whereas when tj! 0, the correlation length becom es of the sam e order as the linear size of the system and the nite-size e ects becom e very strong. Nevertheless, just before the curves bend down, for the largest lattice sizes we can read o that (t) 0:34 0:36. In the case of the susceptibility, for the greatest sizes,  $_{e}$  (†) is stable around 1:34 when †j is not too small, i.e., when the nite-size e ects are not too strong. The plot of e (**†**) vs. the rescaled variable  $L^{1=}$  jjshows that the critical power-law behaviour holds in di erent tem perature ranges for the di erent sizes studied. A s expected, the size e ects are m ore sensitive when the lattice size is small and the critical behaviour is better described when the size increases.

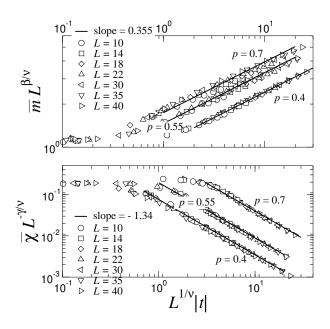

F ig.14.Variation of the tem perature dependent e ective critical exponent  $_{\rm e}$  (jj) = d h =d h jj (in the low tem perature phase) as a function of the reduced tem perature jj (top) and L  $^{1-}$  jj (bottom) for the bond-diluted Ising m odel with p = 0:7 and several lattice sizes L. The horizontal dashed lines indicate the pure and site-diluted values of . The susceptibity vs. the coupling strength K = J=k\_B T in the ordered phase is shown in the upper part.

Table 4. Critical exponent deduced from log-log ts of the susceptibility vs. the reduced temperature j in the ordered phase for the concentrations p = 0.55 and 0.7.

p= 0:55	L	40		22	
	# points	7		12	
	<sup>2</sup> =d.o.f	0.07		1.6	
		1.36(3)		1,36(2)	
p= 0:7	L	40	35	22	18
	# points	10	8	9	8
	<sup>2</sup> =d.o.f	8.37	0.01	80.0	0.81
		1.32(1)	1.34(5)	1.40(4)	1.34 (5)

A more quantitative analysis is possible for the concentrations p = 0.55 and 0.7 for which the most accurate tem perature simulations have been done. >From the tem perature behaviour of the susceptibility, we have directly extracted the power-law exponent from error weighted least-squares ts by choosing the tem perature range that gives the smallest  $^{2}$ =d.o.f for several system sizes. The results are given in Table 4.W e see that all estim ates are consistent with 1:34 1:36, which is clearly di erent from the pure model's exponent of 1:24. In particular we do not observe in this analysis any pronunced di erences between the two dilutions. For p = 0.4, our main dilution closest to the percolation threshold, the number of accurate tem perature points is unfortunately not large enough to allow for reliable ts.

F ig. 15. Log-log plot of the scaling functions m L = (top) and L = (bottom) against L<sup>1=</sup> jrjfor p = 0:4,0:55, and 0:7 in the low-temperature ordered phase (K > K $_{\rm c}^{\rm l}$ ). The lines show the power-law behaviours with the exponents ' 0:355 and ' 1:34 which characterize the disorder xed point. The data for the sm allest values of L<sup>1=</sup> jrjwhich do not lye on the m aster curve show the size e ects described previously when the correlation length is limited by the linear size L.

From the previous expressions of the magnetisation and susceptibility as a function of the reduced temperature and size, following a procedure proposed by B inder and Landau [72] a long time ago, it is instructive to plot the scaling functions f (x) and g (x). For nite size and  $\pm j \in 0$ , the scaling functions may be Taylor expanded in powers of the inverse scaling variable x<sup>1</sup> = (L<sup>1=</sup>  $\pm j$ )<sup>1</sup>, for example in the case of the susceptibility (t; L) =  $\pm j$  [g (1) + x<sup>1</sup>g<sup>0</sup> (1) + 0 (x<sup>2</sup>)], where the amplitude g (1) is usually denoted by . Multiplying by L<sup>=</sup> leads to

$$L = g(x) = x + O(x^{-1});$$
 (14)

where g (x) = x g (x). The case of the m agnetisation is slightly di erent, since the m agnetisation is asymptotically vanishing in the high-temperature phase, and thus m (t;L) =  $\pm j$  [f (1) + x  ${}^{1}f^{0}(1) + O(x^{2})$ ] or

m L = f 
$$(x) = x$$
  
B + B<sup>0</sup>x<sup>1</sup> + O  $(x2)$   
B + B<sup>0</sup>x<sup>1</sup> + O  $(x2)$   
(15)

which should give universal curves for the di erent sizes and tem peratures.

The curves in the ordered phase shown in Fig. 15 are obviously universalmaster curves whose slopes, in a log-log plot, give the critical exponents ' 0:355 and

' 1:34. Indeed, when  $\pm j$ ! 0 but with L still larger than the correlation length , one should recover the critical behaviour given by f (x) x and g (x) x.

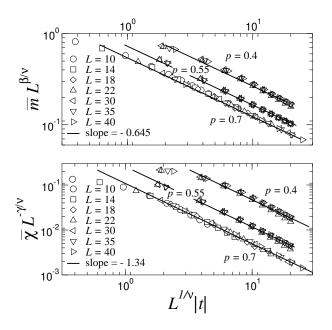

Fig. 16. Log-log plot of the scaling functions m L  $\fi$  (top) and L  $\fi$  (bottom) against L  $\fi$  j in the disordered phase (K < K  $_{\rm c}^{\rm l}$ ) for the three dilutions. The lines show the power-law behaviours with the exponents 1 ' 0:645 and ' 1:34 which characterize the disorder xed point.

The same procedure applied to the two other bond concentrations p = 0.55 and 0.4 gives analogous results and con m s the universal values of the disordered critical exponents and , independent of the concentration as is illustrated in Fig. 15.

In the disordered phase  $K < K_c^1$ , t > 0 the previous scaling assumptions for m and lead to universal functions whose slopes on a logarithm ic scale are equal to 1' 0:645 and ' 1:34, see Fig. 16.

Som e com binations of critical am plitudes are also universal and thus characterize the critical point. In fact, critical am plitude ratios are often m ore sensitive to the universality class than the critical exponents them selves [73]. Am ong such ratios,  $_{+}$  = is directly accessible through our results. An exam ple is illustrated in F ig. 17, where the scaling function of Eq. (11) is plotted against the scaling variable x. The values of the am plitudes which describe the approach to criticality from above and from below,  $_{+}$  and , respectively, are shown in shaded horizontal

$$= = 1:62 \quad 0:10 \ (p = 0:7);$$
 (16)

 $_{+} = = 1:50 \quad 0:10 \text{ (p} = 0:55);$  (17)

$$p = 1:48 \quad 0:20 \quad (p = 0:4) \quad (18)$$

follow. The values obtained for the three dilutions are consistent within error bars but they unfortunately appear to be in contradiction with a eld-theoretic approach of Bervillier and Shpot [60], who predicted a ratio equal to  $_{+}$  = 3.05(32). This is nevertheless not a crucially con icting result, since susceptibility am plitudes of course depend on the de nition used to compute the susceptibili-

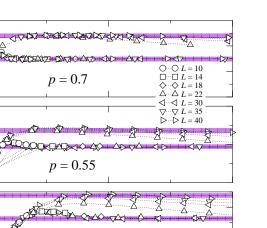

Fig. 17. Log-log plot of the scaling functions tj against to  $L^{1^{-1}}$  in the three dilutions. The shaded horizontal stripes

(< +), respectively.

ities. At any rate, our estimates (16) { (18) for the disordered Ising model are clearly dierent from those for the pure model where  $_{+}$  = obtained with eld-theoretic and high-temperature series expansion techniques varies between 4:70 and 4:95 [74], and a recent high-precision M onte C arlo study [75] concluded that  $_{+}$  = 4:75 (3).

0Č

In this paper, we have reported an intensive M onte C arlo study of the physical properties of the 3D disordered bonddiluted Ising m odel. A s the critical exponents of the pure and disordered m odels are very close, the num erical procedure has to be carefully chosen, especially the therm al averaging and the average over the disorder realisations. W e have determ ined num erically the phase diagram of the disordered m odel, in very good agreem ent with a singlebond e ective-m edium approxim ation.

The non-self-averaging at criticality, as discussed by A harony and Harris, is con med here. At a quantitative level, the discrepancy between the num erical values of the norm alized squared width of the susceptibility R (L) in this work and that in Ref. [44] de nitely com es from the di erence in the de nition of . Although in our case R (L) and to a lesser extent also  $R_m$  (L) do not seem to approach a unique constant independent of the disorder concentration when the system size L increases, we cannot exclude a unique lim iting value when cross-over e ects are properly taken into account. This possibility is corroborated by our nite-size scaling study of critical exponents. A comparison of the underlying disorder distributions for the bond-diluted Ising and q = 4 Pottsm odels shows that the weight of rare events plays a much more crucial role for the critical properties of the latter m odel.

pure percolation	0.45	2.05	

The main emphasis was on investigations of the critical behaviour of the disordered model based on a nitesize scaling study and on a complementary study of the tem perature scaling behaviour. In the st case, we have shown the great in uence of the cross-over phenom ena between the pure, disorder and percolation xed points which lead to the measurem ent of e ective critical exponents dependent on the concentration of magnetic bonds. The temperature study, on the other hand, turned out to be much better behaved and allowed us to con m the unique values of the critical exponents, independent of the concentration and in agreem ent with the site-diluted values, thus providing strong num erical evidence for the theoretically predicted universal behaviour of the two disorder distributions. These results are sum marized in Table 5.A scaling study of the average of the maxim a of the susceptibilities i for each sample instead of the maximum of the average susceptibility would have been an interesting alternative. How ever, it is technically more complicated because from sample to sample the position of the maximum of the susceptibility varies and m ay be far from the simulation tem perature making histogram reweighting unreliable. There should even appear samples with large bonddensity uctuations where unconnected or weakly connected clusters of bonds coexist. Such special con gurations m ay display a double-peaked (or m ore com plicated) susceptibility curve resulting from the independence of these uncorrelated clusters.

Finally, we should remark that even though this work required a really huge amount of e ort and CPU time, for some reasons that we are unable to identify, the accuracy of our results is not as good as in the work of Ballesteros et al. [24] for site-dilution. For example we were not able to conclude for a reliable estimate of the corrections-to-scaling exponent ! as they did. Nevertheless it is worth noticing that the tem perature scaling is quite satisfying and led to the measurem ent of the susceptibility amplitude ratio  $_{+} =$ , a universal combination which was still unknown num erically, and which com plem ents an estim ate of other universal com binations of am plitudes reported recently in Refs. [45,76]. A santicipated from a previous analysis for disordered system s, our estiare clearly di erent m ates for the am plitude ratio  $_+ =$ 

from the pure model and thus yield the cleanest signal for 27. C. Chatelain, PE. Berche, B. Berche, W. Janke, Comp. a unique disorder xed point.
