We respond to the issues discussed by Farmer and Lillo (FL) related to our proposed approach to understanding the origin of power-law distributions in stock price fluctuations. First, we extend our previous analysis to 1000 US stocks and perform a new estimation of market impact that accounts for splitting of large orders and potential autocorrelations in the trade flow. Our new analysis shows clearly that price impact and volume are related by a square-root functional form of market impact for large volumes, in contrast to the claim of FL that this relationship increases as a power law with a smaller exponent. Since large orders are usually executed by splitting into smaller size trades, procedures used by FL give a downward bias for this power law exponent. Second, FL analyze 3 stocks traded on the London Stock Exchange, and solely on this basis they claim that the distribution of transaction volumes do not have a power-law tail for the London Stock Exchange. We perform new empirical analysis on transaction data for the 262 largest stocks listed in the London Stock Exchange, and find that the distribution of volume decays as a power-law with an exponent

$3/2$ in sharp contrast to FL's claim that the distribution of transaction volume does not have a power-law tail. Our exponent estimate of $3/2$ is consistent with our previous results from the New York and Paris Stock Exchanges. We conclude that the available empirical evidence is consistent with our hypothesis on the origin of power-law fluctuations in stock prices.

PACS numbers: 05.45.Tp, 89.90.+n, 05.40.-a, 05.40.Fb

We recently proposed a testable theory for the origin of the empirically-observed power-law distributions of financial market variables such as stock returns, volumes, and frequency of trades [1]. Our theory explains the power-law exponent of the distribution of returns by deriving a square-root functional form for market impact (square-root law) that relates price impact and order size. Our previous empirical analysis gave results that support the square-root law of market impact.

Farmer and Lillo (FL) [2] raise some issues related to the empirical validity of the theory proposed in Ref. [1]. Their discussion is based on the following arguments:

1. FL claim that the price impact function grows slower than a square-root law. Interestingly, FL's empirical analysis does find a power-law relationship for market impact with exponent $1/2$ for volumes smaller than a threshold, consistent with the square-root form of market impact in our theory. However, for large volumes FL claims < 0.2 [for the New York Stock Exchange (NYSE)] and 0.26 [based on analyzing 3 stocks in the London Stock Exchange (LSE)]. FL do not compute error-bars for large volumes, but claim that, from a visual comparison, $= 1/2$ (square-root law) is inconsistent with the data.

2. FL argue that the empirical analysis that we presented in support of the square-root functional form

of market impact [2] is "invalidated" by the long-memory nature of order flow."

3. FL analyze the volume distribution of 3 stocks from the London Stock Exchange and claim that the volume distribution does not follow a power-law. Consequently, FL conclude that volume fluctuations do not determine the power-law tail of returns.

We first outline our responses to these criticisms and then present our detailed response with results of our new analysis.

1. FL find $< 1/2$ for large volumes from analyzing the average value of return for a trade for a given trade size. FL's procedure for estimating price impact is flawed since large orders are usually executed by splitting into smaller size trades, so the procedure used by FL gives a downward bias for the power law exponent defined in our theory [1, 5], giving rise to an apparent exponent value $< 1/2$ smaller than the correct value. In fact FL's procedure gives $< 1/2$ for large volumes precisely the domain in which we expect the order-splitting effect to be dominant and therefore a downward bias for

2. Although we present new estimators to address this point, we believe FL's argument to be incorrect since long-memory in order flow clearly does not

imply the same for returns, so FL's criticisms about our estimation procedure do not seem relevant. To address a potential problem of long memory in order flow, we draw from a new estimator for measuring market impact [3] and extend our previous analysis to the 1000 largest NYSE stocks. Our new estimation confirms that the market impact function does behave as a square-root function of the volume.

3. We analyze 262 largest stocks listed in the London Stock Exchange. Our analysis of volume distribution for these 262 stocks shows that the distribution of volume decays as a power-law with an exponent $\beta=2$ in agreement with our previous results for the NYSE and the Paris Bourse. In fact our analysis of the volume distribution for the same stocks analyzed by FL shows a clear power-law behavior with exponent $\beta=2$ in contrast to FL's claim.

Define S_i as the price of the stock after trade i ,

$$p_i = \log S_i - \log S_{i-1} \quad (1)$$

as the return concomitant to trade i , so the return over a fixed time interval t is

$$r = \sum_{i=1}^N p_i \quad (2)$$

where N is the number of trades in t . Let q_i be the number of shares traded in trade i so

$$Q = \sum_{i=1}^N q_i \quad (3)$$

is the total volume in interval t . We define the trade imbalance

$$\sum_{i=1}^N \epsilon_i q_i \quad (4)$$

where $\epsilon_i = 1$ indicates a buyer-initiated trade and $\epsilon_i = -1$ denotes a seller-initiated trade. We denote by V the size of a large order, which can be executed in several trades.

1. Measuring market impact

Let Δp be the change in price caused by a large order of size V , all else remaining the same. Our theoretical approach [1] derives a power-law functional form for the market impact function [8],

$$\Delta p \propto V^\beta \quad (5)$$

We hypothesized $\beta = 0.5$ and supported the hypothesis by empirical analysis.

Our hypothesis Eq. (5) pertains to Δp , the total impact in price of a large order of size V . In practice, as outlined

in Ref. [1], large orders are executed by splitting into orders of smaller size which are observed in the trade time series as the trade size q_i . The empirical analysis of Refs. [2] and [4] refer to the relationship local price change $E(\Delta p|q)$ and not the price impact $E(\Delta p|V)$ that we are interested in. The true market impact function $E(\Delta p|V)$ is indeed notoriously difficult to measure since the information about the unsplit order size is usually proprietary and not available, neither in our data nor in the data analyzed by FL.

FL claim that the price impact function grows more slowly than a square-root function for large volumes. The basis for their claim is the analysis presented in Ref. [4] that $E(\Delta p|q) \propto q^\alpha$ with $\alpha = 0.5$ for small q and $\alpha = 0.2$ for larger q . While $E(\Delta p|q)$ indeed grows less rapidly than a square-root, as reported in Ref. [14], $E(\Delta p|q)$ neither quantifies price impact of large trades, nor does it contradict our theory and empirical results [1]. This is because a trade by trade analysis of $E(\Delta p|q)$ leads to a biased measurement of full price impact and the exponent α , since it does not take into account the splitting of trades [1, 5].

Consider an example. Suppose that a large fund wants to buy a large number V of shares of a stock whose price is \$100. The fund's dealer may offer this large volume for a price of \$101. Before this transaction, however, the dealer must buy the shares. The dealer will often do that progressively in many steps, say 10 in this example. In the first step, the dealer will buy $V=10$ shares, and the price will go say, from \$100 to \$100.1, and in the second the price will go from \$100.1 to \$100.2. After some time elapses, the price will have gone to \$101 in increments of \$0.1. At this stage, the dealer has his required number of shares, and hands them over to the fund manager at a price of \$101. The true price impact here is 1%, since the price has gone from \$100 to \$101. But in any given transaction, the price has moved by no more than \$0.1. So Ref. [2] would find an "apparent" price impact of no more than \$0.1, i.e. 0.1% of the price. Since as the transaction is executed the price of the stocks goes from \$100 to \$101, the true price impact is 1%. As a result the procedure of FL will measure a value 10 times smaller than the true value. This downward bias explains why FL find in Fig. 2 a maximum impact of 0.1% | a very small price impact. Other evidence in economics [11, 12] finds impacts that are up to 40 times larger than that of FL's analysis. Likewise our evidence pertains to large impacts, captured by Fig. 2 of our paper which shows on the vertical axis values of r^2 equal up to $\sqrt{200}$ times the variance σ^2 , i.e., values of return r up to $\sqrt{200} \approx 14$ standard deviations.

We can quantify the bias in the above example. Suppose that a trade of size V is split into $K = V/q$ (10 in our example) trades of equal size $q = V/K = V^{1-\alpha}$, with $0 < \alpha < 1$. Then the apparent impact Δp incurred by each trade (0.1% in our example) will be $1/K = (1/10)$

in our example) of the total price impact V (1% in our example), i.e. $p = V = K = V$. So a power law fit of p vs q , such as the one presented in Fig. 2 of FL, will give $p \propto q^\beta$ with [6]

$$\beta = \left(\frac{1}{\alpha} \right) = (1 - \alpha) < 1 :$$

The "trade by trade" measurement of the price impact, as performed by Ref. [2, 4], leads to a biased measurement of the exponent of the true price impact.

It is to address this bias that we examine $E(r^2 | Q)$ in Ref. [1]. As is well established empirically, the sign of returns is unpredictable in the short term, so the reasoning in Ref. [5] shows that $E(r^2 | Q)$ will not be biased [9].

Our analysis [1] was presented with data for the 116 most actively traded stocks. To check if the result of $\beta = 0.2$ for large volumes presented in Refs. [2] and [4] could arise from increasing the size of the database, we now extend our analysis to the 1000 largest stocks in our database for the 2-yr period 1994-95. Figure (a) confirms that $E(r^2 | Q) \propto Q$ as predicted by our theory.

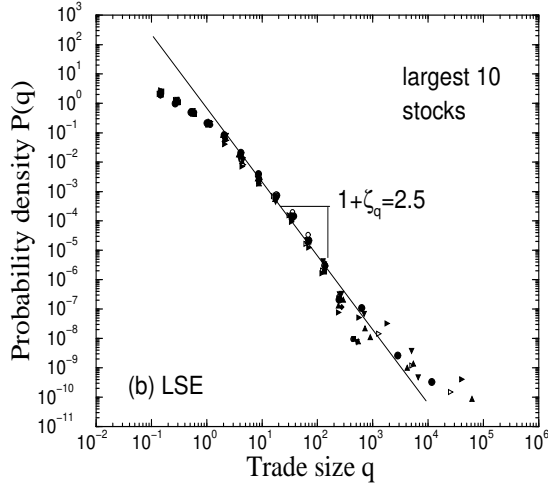

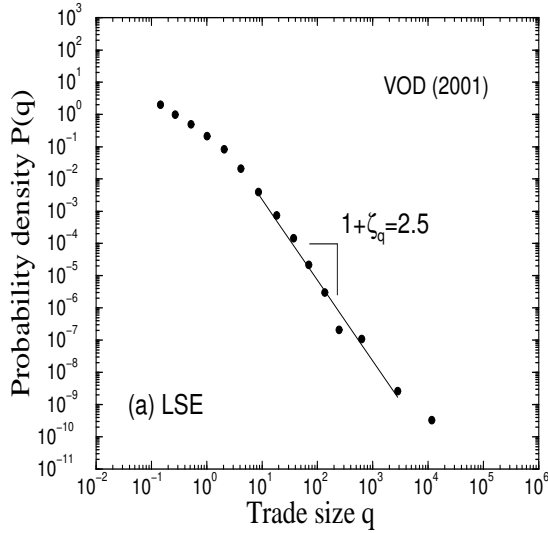

FIG. 1: (a) Conditional expectation function $E(r^2 | Q)$ of the squared return for a given volume for $\Delta t = 15$ min for 1000 largest stocks in the NYSE, Amex and NASDAQ for the period 1994-95. We have normalized r for each stock to zero mean and unit variance, and Q is normalized by its first centered moment. This normalization procedure allows for a data collapse for different stocks and the plot represents an average for 1000 stocks. Regressions in the range $3 < Q < 70$ give values of the exponent $\beta = 1.05 \pm 0.08$. (b) Conditional expectation function $E(r^2 | q_{\max})$ of the squared return for a given q_{\max} for $\Delta t = 15$ min. Here q_{\max} is the largest trade size in the 15 min interval. Power-law regression gives the value of the exponent $2 = 1.09 \pm 0.06$ consistent with $\beta = 0.5$. (c) Conditional expectation function $E(r^2 | q_{\max})$ of the squared return for a given q_{\max} for fixed number of trades $N = 40$. Power-law regression gives the value of the exponent $2 = 1.10 \pm 0.06$. Source: Ref. [3].

2. Robustness of estimation against long-memory of order flow

FL argue that the empirical analysis that we presented in support of the square-root functional form of market impact is "invalidated" by the "long-memory nature of order flow". FL's argument is based entirely on the assumption that returns due to each transaction i can be written as $r_i = \epsilon_i q_i$ where $\epsilon_i = 1$ for a buy trade and $\epsilon_i = -1$ for a sell trade. Under this assumption, FL then argue that our estimator $E(r^2 | Q)$ is affected by the long-range correlations in the trade signs ϵ_i [2, 15]. FL give some empirical evidence for this potential effect for small to moderate volumes.

All of the tests shown by FL are for a fictitious return f_i constructed on a trade-by-trade basis as $f_i = \epsilon_i q_i$. FL's argument and the tests shown in Fig. 1 of FL are for the fictitious return. In reality, return can certainly not be expressed as $r_i = \epsilon_i q_i$, with ϵ_i being the trade indicator. Indeed, if this were true, returns themselves would be long-range correlated—a possibility long known to be at odds with empirical data. Since the sign of

In addition to the above, to ensure that our estimation is robust to varying number of trades in a fixed t , we have computed $E(r^2 | \mathcal{H}_{n,ax})$ for fixed number of trades instead. Figure (c) shows that $E(r^2 | \mathcal{H}_{n,ax}) \propto q_{n,ax}^{-1}$ for r over $N = 40$ trades.

We would like to emphasize that in Fig. 2 we consider very large trades that are up to 70 times the first moment of volume. They correspond to returns of up to 14 standard deviations of returns. This confirms that we study very large trades and returns – the ones that are relevant for the study of power law fluctuations, while in contrast FL's analysis does not systematically treat large trades.

We conclude that the procedure used in Ref. [2] has a downward bias of the price impact of large trades. When we perform more appropriate analysis, we confirm that the $\beta = 2$. This corroborates our hypothesis [1, 5] that large fluctuations in volume cause large fluctuations of prices.

3. Half-cubic power-law distribution of volumes

The last claim of FL pertains to the very nature of the volume distribution. They present the results of their analysis of three stocks in the London Stock Exchange and claim their analysis shows no evidence for a power-law distribution.

We analyze the same database which records all trades for all stocks listed in the London Stock Exchange. From this database, we first examine one stock {Vodafone, VOD} which is analyzed by FL. For this stock, we compute the volume distribution and find clear evidence for a power-law decay [Fig. 2 (a)]

$$P(q) \propto q^{-\zeta_q - 1} \quad (7)$$

with exponent $\zeta_q = 1.5 \pm 0.1$, in agreement with our previous results for the NYSE and the Paris Bourse [1, 13], but in sharp contrast to the FL results who claim a thin-tailed distribution for the same data.

the return r_i and that of the trade sign s_i are clearly not equal, FL's argument about our estimation procedure being affected by the long-memory nature of the trade sign (s_i) is incorrect (See Ref. [15] on a related point).

Although FL's argument is incorrect, to address the more general concern that the autocorrelations of the trade signs s_i might bias our analysis, we draw from a forthcoming paper [3], which performs the following analysis [7]. For each interval t define $q_{n,ax}$ as the size of the largest trade. In our theory, if the largest trade $V_{n,ax}$ is large, it will have a them a \propto influence on the value of return, so that one will have $r^2 \propto V_{n,ax}^2 \propto q_{n,ax}^2$. Hence $q_{n,ax}$ gives us a diagnostic value of the behavior of the largest trade, independently of a potential collective behavior. We detail this in Ref. [3]. We compute $E(r^2 | \mathcal{H}_{n,ax})$ and find [Fig. (b)].

$$E(r^2 | \mathcal{H}_{n,ax}) \propto q_{n,ax}^{-1} \quad (6)$$

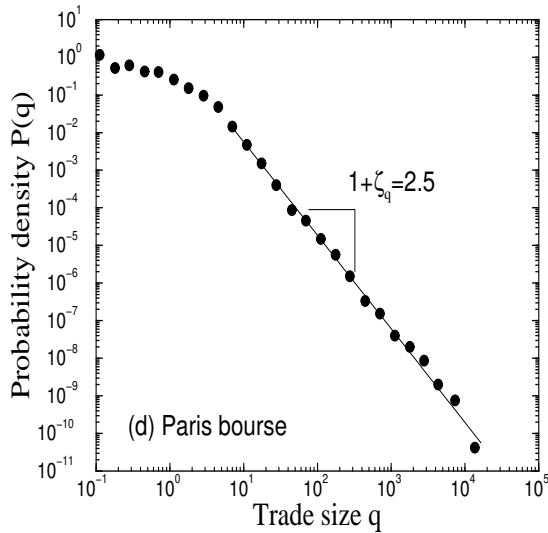

FIG. 2: (a) Probability density function of trade volumes for Vodafone Inc. (VOD) for 2001. A power-law fit in the region $10 < q < 1000$ gives value of the exponent $\zeta_q = 1.5 \pm 0.1$. In contrast FL finds much more rapid decay. (b) Probability density function of trade volumes for 10 largest stocks listed in the London Stock Exchange, showing clear evidence of power-law decay with exponent $\zeta_q = 1.5 \pm 0.1$, consistent with our previous results [13] for the New York Stock Exchange and for the Paris Bourse. Here q are normalized by its first centered moment, so all 10 distributions collapse on one curve. We find an average exponent $\zeta_q = 1.59 \pm 0.09$. (c) Same as (b) for all 265 stocks in our sample where q is normalized for each stock by its first centered moment. We find $\zeta_q = 1.4 \pm 0.09$. (d) Probability density function of trade volumes for 30 largest stocks listed in the Paris Bourse obtained by the same procedure. We find $\zeta_q = 1.49 \pm 0.03$ [5].

For the 10 largest stocks in our sample, Fig. 2(b) shows that $P(q)$ is consistent with the same power-law of $\zeta_q = 3/2$ consistent with our earlier finding for the NYSE [13]. We extend our analysis to the 265 largest LSE stocks and find similar results [Fig. 2(c)].

To test the universal nature of this distribution, we analyze data for 30 largest stocks listed in the Paris Bourse and find that $P(q)$ is consistent with the a power-law with almost identical exponents $\zeta_q = 3/2$ [Fig. 2(d)].

In summary, the analysis of Ref. [2] pertains to small to moderate trades. FL's estimation is biased for large trades, so FL can detect only very small price impacts, less than 0.1%. When we use our more general procedure and study significantly larger data, we confirm our initial finding of a square root price impact function. We conclude that the available evidence is consistent with our hypothesis [1, 5] that large fluctuations the volume traded by large market participants may contribute significantly to the large fluctuations in stock prices [3].

Acknowledgments. We thank the NSF's economics program for financial support, and Joel Hasbrouck, Carl Hoptman, Gideon Saar, Jeannette Wurgler and especially Gilles

Zumbach for helpful conversations and help with obtaining the data analyzed.

Note added in press: After our initial submission, it has become clear that FL's claim of a non-power-law distribution of trade sizes [2] for the LSE stocks is based on incomplete data. FL's analysis excludes the upstairs market [16] trades which contain the largest trades in the LSE. In contrast, our result of a $3/2$ power-law exponent for the volume distribution is based on data containing all trades (both the upstairs and the downstairs market trades) in the LSE. By excluding the large trades in the upstairs market, FL set an artificial truncation at large volume, so FL's finding of a non-power-law distribution of volume is merely a trivial artifact of incomplete data. Although FL claim in their note added that "it has been shown that large price fluctuations in the NYSE (including the upstairs market) and the electronic portion of the LSE are driven by fluctuations in liquidity" their new analysis and findings are tainted by the same problems as in their present comment: (i) incompleteness (absence of the upstairs market trades) of the data analyzed and (ii) they do not take into account the splitting of large orders.

Gabaix et al. [1, 5] and FL [2] discuss two distinct possibilities respectively: (i) large price changes arise from large trades and (ii) large price changes arise from fluctuations in liquidity [14, 17]. While we believe that both mechanisms play a role in determining the statistics of price changes, our empirical findings support the possibility that the specific power-law form of the return distribution arises from large trades.

 - [6] The inequality below holds if $\alpha < 1$. There is wide agreement that α should be no greater than $1/2$. This is because the power law exponent of returns α_r and the power law exponent of volumes satisfy $\alpha_r + \alpha_v = 1$, so that the empirical values $\alpha_r = 2/3$ imply $\alpha_v = 1/3$.
 - [7] We are detailing the foundations of this analysis in Ref. [3]. The specifics of the split matter in principle. In Ref. [1] we present a theory of power law splitting in which the size of the largest chunk, q_{max} , is proportional to the size of the entire order, V .
 - [8] As in Ref. [1], we interpret $p(V)$ to mean that there

exist a slowly varying function $L(V)$ such that for large V , $p = V^{-L(V)} \rightarrow 1$. A function is called slowly varying when for all $t > 0$, $\lim_{V \rightarrow \infty} L(tV)/L(V) = 1$. Typical slowly varying functions are $L(V) = a$, or logarithmic corrections: $L(V) = a \ln(V)$, where a and \ln are constants.

- [9] Our theory is one of large trades. The evidence presented in Ref. [2] pertains to small to moderate size trades. It follows a long tradition pioneered by Ref. [10] (see also [14, 15]), and may be new for small to moderate trades. The issue of splitting may be less important for those trades, but it is almost certainly crucial for large ones (e.g., trades bigger than 5 to 10 times the average trade size). This is why the trade by trade $E(p_j)$ measurement has a downward bias for large trade, which is avoided when we take $E(r^2 | \mathcal{D})$.
