(Dated: March 22, 2004)

Many of the large structures of the cell, such as the cytoskeleton, are assembled and maintained far from equilibrium. We study the stabilities of various structures for a simple model of such a far-from-equilibrium organized assembly in which spherical particles move under the influence of attached motors. From the variational solutions of the many-body master equation for Brownian motion with motorized kicking we obtain a closed equation for the order parameter of localization. Thus we obtain the transition criterion for localization and stability limits for the crystalline phase and frozen amorphous structures of motorized particles. The theory also allows an estimate of nonequilibrium effective temperatures characterizing the response and fluctuations of motorized crystals and glasses.

Assemblies of molecular sized particles are seldom far from equilibrium owing to the relative strength of the thermal fluctuating inherent at this scale. As we consider assemblies of larger and larger particles the thermal forces become less capable of moving and reorganizing such assemblies. At the size scale of biological cells, objects are not rearranged just by equilibrium thermal forces but are moved about by motors or by polymerization processes that use and dissipate chemical energy [1]. What are the rules that govern the formation of periodically ordered or permanently organized assemblies at this scale? Does the far-from-equilibrium character of the fluctuating forces due to motors and polymer assembly change the relative stability of different colloidal phases? These problems are not unique for intracellular dynamics, but belong to an emerging family of nonequilibrium assembly problems ranging from driven particles [2], swarms [3], and jamming [4, 5], to microscopic pattern formation and mesoscopic self-organization [6].

Motivated by these considerations which may be relevant for the dynamics of the cytoskeleton [1, 7] as well as other far-from-equilibrium aggregation systems, we study a simple motorized version of the standard hard sphere fluid often used to model colloids. Both motors and nonequilibrium polymer assemblies can convert the chemical energy of high energy phosphate hydrolysis to mechanical motions which one would ordinarily think would "stir" and hence destabilize ordered structures. We will show these systems in some circumstances may have an enlarged range of stability relative to those with purely thermal motions.

We adopt a stochastic description of the motions of a collection of motorized particles. The overdamped Langevin dynamics is  $\dot{\mathbf{r}}_i = D \mathbf{f}_i + \tilde{\mathbf{v}}_i^m(t) + \tilde{\mathbf{v}}_i^n$ . Here  $\mathbf{r}_i$  is the position of the  $i$ th particle,  $\mathbf{f}_i = -\nabla U(\mathbf{r}_i)$  is the mechanical force that comes from the usual potential  $U(\mathbf{r}) = U(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n) = \sum_{i,j} u(\mathbf{r}_{ij})$  among particles. The random variable  $\tilde{\mathbf{v}}_i^n$  vanishes on average and is Gaussian with  $\langle \tilde{\mathbf{v}}_i^n(t) \tilde{\mathbf{v}}_j^n(t') \rangle = 2D \delta_{ij} \delta(t - t')$ . The

motor term  $\tilde{\mathbf{v}}_i^m(t) = \sum_q^P \mathbf{v}_q(t - t_q)$  is a time series of shot-noise-like kicks. Its properties depend on the underlying biochemical mechanism of the motors. The stochastic nature of the motors also leads to a master equation description [8, 9] for the dynamics of the probability distribution function of the particle configurations,

$$\frac{\partial}{\partial t} (\hat{L}_{FP} + \hat{L}_{NE}) \rho(\mathbf{r}; t) = 0 \quad (1)$$

Here  $\hat{L}_{FP} = D \sum_i \nabla_i \cdot \nabla_i$  ( $\nabla_i = \nabla_{\mathbf{r}_i}$ ) is the Fokker-Planck operator. An integral operator  $\hat{L}_{NE} \rho(\mathbf{r}) = \int d\mathbf{r}' \sum_i K_{f\mathbf{r}g!}(\mathbf{r}, \mathbf{r}') K_{f\mathbf{r}g!}(\mathbf{r}', \mathbf{r}) \rho(\mathbf{r}')$  summarizes the nonequilibrium kicking effect of the motors.

The motors are simply built in the particles. They work by consuming chemical energy sources, like ATP. In a single chemical reaction event, the motor makes a power stroke (which induces a discrete conformational change) that moves the particle by a distance of  $\lambda$  in the direction  $\hat{\mathbf{n}}$ . Motor kicking can be modeled as a two-step stochastic process: step I, the energy source binds to the motor, and the step II, the reaction ensues and the resulting conformational change makes a power stroke. The rate of the first step  $k_1$  depends on the energy source concentration while the rate of the second step  $k_2$  depends on the coupling between the structural rearrangement and the external forces,  $k_2 = \exp(s[U(\mathbf{r}) - U(\mathbf{r} + \lambda \hat{\mathbf{n}})])$ , i.e., motors slow down when they work against mechanical obstacles. Such slowing has been demonstrated in the case of microtubules [10, 11].  $s$ , the coupling strength, measures the relative location of the transition state for the power stroke step and ranges from 0 to 1. At the limit  $s \rightarrow 1$  we have a susceptible motor and while  $s \rightarrow 0$  corresponds to an adamant motor. We use these names in the sense that an adamant motor is not sensitive to its thermal mechanical environment, so each power stroke uses and wastes a lot of energy; in contrast a susceptible motor saves energy running faster downhill (free energy) and slower uphill.

We assumed that step II is the bottleneck of kinetic-

ics, i.e., the overall rate  $k = k_2 - k_1$ . To make our model suitable for a variety of situations, we specify different variables  $s$  and  $s^0$  for the degree of susceptibility for going uphill and downhill respectively. Thus  $k = \exp(-G[U(\mathbf{r} + \hat{\gamma}) - U(\mathbf{r})])$  with a switch function  $G(x) = (x)sx + (1-x)sx$ . Here  $s$  is the Heaviside function. Thus the overall temporal statistics of the kicks is position-dependent Poisson distribution.

The kicking direction  $\hat{n}(t)$  fluctuates on the time scale of the particle tumbling. We will study below explicitly two extremes: the isotropic kicking case when  $s$  is very small and the persistent kicking case when  $s$  is very large compared with  $s^0$ , i.e., each motor always kicks in a predefined direction. The direction of persistence will be assumed to vary randomly from particle to particle.

To solve the dynamics of probability distributions, researchers often pose the problem as the solution of a variational problem. Due to the  $\hat{L}_{NE}$  part of eqn. (1), we can not perform the usual transformations of the left and right state vector to make  $\hat{L}$  hermitian [9]. For this type of problems, nevertheless we can obtain the solution of the many-particle master equation using nonhermitian variational methods as described by Eyink [12, 13] or using the squared (therefore hermitianized) operator  $\hat{L}^v \hat{L}$  (e.g., p159 of [9]).

Eyink's nonhermitian variational formulation is similar to the Rayleigh-Ritz method in ordinary quantum mechanics but uses independent left and right state vectors. For isotropic kicking, we start with a Jastrow-like trial function

$$(\mathbf{f}|\mathbf{r}\mathbf{g}) = \exp \left( \sum_i X [\mathbf{r}_i - \mathbf{R}_i]^2 \right) U(\mathbf{f}|\mathbf{r}\mathbf{g}) \quad (2)$$

Similar to the quantum hard spheres [14], such a trial function avoids any singularities of  $\hat{L}_{FP}$  arising from the hardsphere potentials  $u_{ij}(\mathbf{r}_{ij})$  between particles  $i$  and  $j$  used in this study. For simplicity, we set  $\mathbf{q}_i = \mathbf{r}_i - \mathbf{R}_i$  and a uniform  $\hat{u}_i = 1$ . The nonhermitian variational method implies for steady states that the second moment of  $\mathbf{q}$  satisfies the moment closure [15] equation

$$\frac{\partial \langle \mathbf{q}_j^2 \rangle}{\partial t} = \langle \hat{L}_{FP}^2 \rangle + \langle \hat{L}_{NE}^2 \rangle = 0 \quad (3)$$

To effectively evaluate eqn. (3), we need to simplify the many-body integration  $\int d^3 \mathbf{q}_i$  involving  $\exp U(\mathbf{f}|\mathbf{r}\mathbf{g})$ . Here we use cluster expansion [16, 17] to render the manybody Boltzmann factor a product of effective single body terms by averaging over the neighbors' fluctuations. We thus have  $\hat{u}_i = \int d^3 \mathbf{u}_i \exp \hat{u}_i$ . Here the original  $u_i = \sum_{j \neq i} \frac{1}{2} u_{ij}$  depends on the manybody configuration, while  $\hat{u}_i$  depends on  $\mathbf{q}_i$  (and constant  $\mathbf{f}|\mathbf{r}\mathbf{g}$ ) only. In fact, we keep it to the harmonic order for consistency, i.e.,  $\hat{u}_i = \frac{1}{2} \mathbf{q}_i^2$ . Here  $s$  is the effective spring constant from the mechanical feedback from neighbors.  $s$  depends on its neighbors' overall fluctuations controlled by  $\sim$  and their mean position  $\mathbf{f}|\mathbf{r}\mathbf{g}$ . In turn, the positions of the

neighbors are controlled by the lattice spacing for crystals or radial distribution functions for glasses and ultimately by the nature of the structure and the particle density  $n$ . I.e., for fcc lattice, we have  $c_r = c_r(\sim; n)$  as the eigenvalues of the Hessian matrix constructed from the effective potential  $\frac{1}{2} \sum_{j \neq i} v(\mathbf{R}_j - \mathbf{r})$ . Here  $v(\mathbf{R}; \sim) = \ln[1 + \frac{1}{2} \text{erf}[(\mathbf{R} - \mathbf{r}) \cdot \hat{\gamma}] + \frac{1}{2} \text{erf}[(\mathbf{R} + \mathbf{r}) \cdot \hat{\gamma}] + \frac{(\sim)^{1+2}}{2R}] \exp[-(\mathbf{R} - \mathbf{r})^2 - (\mathbf{R} + \mathbf{r})^2]$  and the sum of  $\mathbf{R}_j$  is over the 12 nearest neighbor positions of the origin of a fcc lattice (with lattice spacing  $(\frac{4}{n})^{\frac{1}{3}}$ ). For glasses [18, 19], we replace the summation over discrete crystalline neighbor location with a mean-field average over the first shell of the pair distribution function of the hardsphere liquids,  $g_1(\sim; n) = \frac{n}{6} \int_{1st:sh} g(\mathbf{R}; n) \text{Tr} \mathbf{r} \cdot \mathbf{v}(\mathbf{R}; \sim) d\mathbf{R}$ . For numerical work, we take  $g(\mathbf{R}; n)$  as the Verlet and Weis's corrected radial distribution function [21].

After some calculations, we obtain the steady-state manybody probability distribution function as a product of localized Gaussians of the form  $\exp[-(\mathbf{r}_i - \mathbf{R}_i)^2]$  with  $\sim$ , the natural localization strength, satisfying two equations:

$$\sim = \sim + (\sim; n) \quad (4)$$

$$6D \frac{1}{\sim} + I_2(\sim) - \left(\frac{1}{\sim}\right)^{3+2} = 0 \quad (5)$$

The first and second terms of eqn. (5) come from  $\frac{h_2^2 \hat{J}_{FP} \cdot \mathbf{j} \cdot \mathbf{i}}{h_1 \mathbf{j} \cdot \mathbf{i}}$  and  $\frac{h_2^2 \hat{J}_{NE} \cdot \mathbf{j} \cdot \mathbf{i}}{h_1 \mathbf{j} \cdot \mathbf{i}}$  respectively. The integral  $I_n(\sim) = \int d^3 \mathbf{q} [(\mathbf{q} + \hat{\gamma})^n - \mathbf{q}^n] \exp[-\mathbf{q}^2 + G(2\sim \hat{\gamma} \cdot \mathbf{q} - \sim^2)]$  can be further expressed as explicit but complicated analytical formulas with incomplete Gamma functions. Thus using eqn. (4) in eqn. (5), we finally derive the order parameter for localization,  $\sim$ , in a closed form with parameters  $\sim; D; \sim; s; s^0$  and  $n$ . When  $\sim = 0$ , we have  $\sim = 0$  and the equilibrium equation  $\sim = (\sim; n)$ , which returns to the self-consistent phonon solution [16, 17, 18, 19, 20]. A nonzero solution  $\sim$  of eqn. (5) is only obtained at sufficiently high density, i.e., for  $n > n_c$ . For low density, the system cannot support stable localized vibrations and is in the fluid phase with  $\sim = 0$ . An instability density  $n_c$  separates these two phases. This phase transition is first-order like, characterized by a discontinuous jump of  $\sim$ .

We calculated  $n_c$  as a function of two independent parameters  $s$  and  $s^0$ ,  $n_c(s; s^0)$  for various  $D$ , and  $\sim$ . An important dimensionless ratio  $\sim^2 = D$  measures the strength of chemical vs. thermal noise. For an actin polymer solution [1], we can relate the effective kicking rate to the speed of nonequilibrium polymerization. Here  $\sim$  is the monomer size 0.01  $\mu\text{m}$ . ( $\sim = 10^{-6}$ ) The treadmill concentration is  $c_r = 0.17 \text{ M}$ . The chemical reaction rates of the barbed and pointed ends of actin are  $k_+ = 11.6 \text{ M}^{-1} \text{ s}^{-1}$  and  $k_- = 1.3 \text{ M}^{-1} \text{ s}^{-1}$  respectively. The diffusion constants of rod are given by the Kirkwood equation [22]. This equation relates

the diffusion to solvent viscosity  $\eta_s$  and gives the translational diffusion constants:  $D_k = k_B T \ln(L/d)/(2\eta_s L)$  and  $D_r = D_k/2$ . Using the typical length of the actin filaments  $L = 20 \text{ nm}$  and typical width  $d$  of about  $0.015 \text{ nm}$ . An estimate of the hydrodynamic diffusion along the rod gives  $D_k = 0.1 \text{ m}^2 \text{ s}^{-1}$ . Thus for a dilute solution of typical actin filaments,  $\lambda = 10^3 - 10^2$ . However, in vivo, the actin monomer concentration is kept much higher than  $c_{cr}$  (with the help of capping proteins which prevent actin filaments from growing longer). Also the viscosity of the cell medium is higher than  $\eta_s$  of pure water due to the presence of other macromolecular components. These lower the effective diffusion constant and raise the value of  $\lambda$ , and therefore they could push  $\lambda$  above 1. The limit  $\lambda = 1$  corresponds to entirely motorized motion.

The resulting densities  $n_c(s; s^0)$  are shown in Fig. 1 and 2. Figure 1 shows some 1D plots that come from vertical slices of  $n_c$  for several special cases. Figure 2 shows the 2D top-view of the critical surfaces  $n_c$  for variety of parameters. For the case shown with  $\lambda = 1$ ,  $(n)$  (which is the only  $n$  dependent part of  $\sim$ ) drops to zero, while we still have a nonzero solution  $\sim =$  for a corner of  $(s; s^0)$  space. In the opposite corner we stopped searching for solutions when  $n_c$  approached the maximum packing density  $\phi = 2$ . Thus we have three distinct regions.

As seen from these figures, kicking noise does not always destabilize the structures. Instead the localized phases have an enlarged stability range when  $s + s^0 > 1$ . When  $s^0 = 1 - s$ , the same stability limits are obtained as in the equilibrium thermodynamic theory. Both the frozen disordered glass and the ordered fcc lattice can be stabilized by kicking motors. The motor effects on the fcc lattice are more pronounced. The fcc phase has a larger stable region than the glass.

Besides the Eyring variational method, we also calculated  $\sim$ ,  $\lambda$ , and therefore  $n_c$  by another method. From the mechanical feedback procedure, we first obtain the mapping from a hard sphere environment to an effective harmonic potential  $\sim = \langle \sim \rangle$ . Here  $\sim$  depends on the steady-state probability distribution of its neighbors. Conversely  $\sim$  can be viewed as the naive effective spring constant of a kicking particle in an harmonic potential of  $\sim$ . Next we numerically solve  $\sim = \langle \sim \rangle$  from single particle master equations using a variational method based on the square hermitianized operator  $\hat{P} \hat{P}^\dagger$  with single particle trial functions. The two sets of operations are iterated to obtain a pair of self-consistent results  $(\sim; \lambda)$ . The critical density predicted by this self-consistent squared hermitian variational method agrees very well with results from the nonhermitian variational method. The difference of instability density is less than 0.1% when  $\lambda < 1$ . The corresponding critical  $\sim_c$  are also similar. The two methods do give different results when  $\lambda > 1$ .

For persistent kicking, the trial functions have to be modified. Each localized particle now has a distribution of locations of the form  $G(\mathbf{r}^0 = \mathbf{r}^0 - \mathbf{b}; \overline{\mathbf{r}}) \exp(-\overline{\mathbf{a}} : \mathbf{r}^0 - \mathbf{r}^0)$ . Here  $\mathbf{b}$  is an off-center shift vector parallel to  $\hat{n}$ . We must consider the effects of the variational parameter

FIG. 1: The instability density of the motorized fcc lattice and the glass as functions of the coupling parameters for these cases i)  $s = 0$  ii)  $s^0 = 0$  and iii)  $s = s^0$ . In these plots there is 3D isotropic kicking with  $D = 0.1$ ,  $\lambda = 10$ , and  $\eta = 0.05$ . Therefore  $\lambda = \frac{\eta^2}{D} = 0.25$ . The two horizontal lines are the corresponding equilibrium ( $\eta = 0$ ) cases.

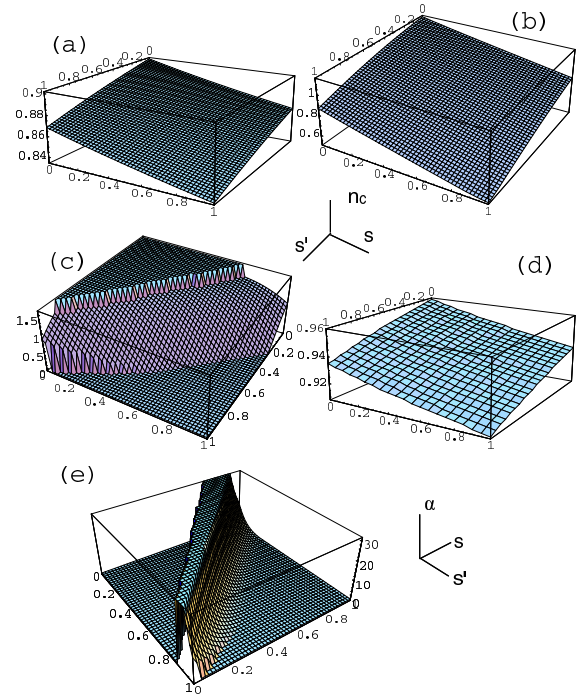

FIG. 2: The instability densities  $n_c(s; s^0)$  surface are shown for motorized fcc lattice cases: (a)  $\lambda = 0.25$ , (b)  $\lambda = 2.5$ , (c),  $\lambda = 25$  and a glass case (d)  $\lambda = 0.25$  for the 3D isotropic kicking with  $\lambda = 10$  and  $\eta = 0.05$ . The corresponding surface for the Lindemann parameter  $\alpha_c(s; s^0)$  of the case of (c) is shown in (e).

FIG. 3: The instability density of the persistent motorized fcc lattice and the glass as parametric functions of  $b$ , which depends on  $\Delta$ . Here  $\Delta = 0.05$ . Both are bounded with middle line  $s + s^0 = 1$ , with upper and lower bound  $s = s^0 = 0$  and 1 respectively.

$b$  on along with the direct changes of  $\bar{a}$ . The additional decrease of  $\bar{a}$  arises from the distortion of the structures caused by always kicking in the same directions. We model the distortion effect of persistent kicking on the pair distributions by replacing each initial position with a dispersed distribution. For the crystal, this means the initial neighboring position of  $R_j$  is replaced by an average over positions  $R_j + b\hat{n}$  with  $\hat{n}$  is an arbitrary unit direction. Likewise, the radial distribution function of the glass case is broadened from the initial  $g_{b=0}(r)$  to  $g_b(r) = g_{b=0}(r^0) \left(\frac{1}{4} \frac{1}{b^2}\right) \left(\int_{-\infty}^{\infty} r_j - b \right) dr^0$ . In this case an additional normalization of the first peak enforces the condition  $g(r) = 0$  for  $r < 1$ :

For persistent kicking,  $s$  has similar effects on  $\bar{a}$  as were found for the isotropic case. The shift  $b$  agrees quite well (within several percentages for the practical range of parameters) with the estimate  $\frac{\Delta}{2D}$  based on a small  $\Delta$  expansion of the master equation. The resulting displacement amplitude  $b$  is large enough to distort the stable structure so that any increased stability that may arise from kicking (if any) is now very modest as shown in Fig. 3.

Since the kicking noise enlarges the stability region in the isotropic case with  $s + s^0 > 1$ , we wondered whether susceptible kicking may sometimes actually decrease the effective temperature of this nonequilibrium system. An effective temperature can be defined by the fluctuation-dissipation relation even for far-from-equilibrium situations like the motorized crystal [23]. The ratio of the thermal temperature to the effective temperature is also called FDT violation factor. The effective temperature can be computed by comparing the fluctuations of a motorized particle to its response to an external force.  $T^{eff}$  depends on the frequency or time duration, the absolute time (in case of an aging system) and even possibly on the choice of the observable itself. To compute the needed time-dependent quantities, we solve the time-dependent master equations for nonhermitian operators, again using a Gaussian ansatz characterized now with dynamic first and second moments.

For illustration, we carry out the analysis of the dynamics for the one dimensional symmetric case in a harmonic potential  $x^2$  with  $s = s^0$ . Thus  $\hat{L}_{PF} = D \partial_{xx}^2$  and  $\hat{Q}[Df^h(x)]$  and  $\hat{L}_{NE}(x) = \frac{1}{2}(x - \langle x \rangle) e^{(x - \langle x \rangle)}$  and  $\frac{1}{2}(x + \langle x \rangle) e^{(x + \langle x \rangle)}$  with  $\langle x \rangle = \frac{1}{2} \int_{-\infty}^{\infty} x e^{(x - \langle x \rangle)} dx$ . The parameters in the Gaussian ansatz  $\langle x; m(t) \rangle = [2m_2(t)]^{-1/2} \exp \frac{[x - m_1(t)]^2}{2m_2(t)}$  with  $m_2 := m_2 - m_1^2$  and  $m_i = x^i$  satisfy the time-dependent dynamics described by a set of differential equations with  $K = \exp(-s^2)$ :  $\partial_t m_1 = -2D m_1 - K e^{2(s - \langle x \rangle)^2 m_2} \sinh(2s m_1)$  and  $\partial_t m_2 = 2D - 4D m_2 + K e^{2(s - \langle x \rangle)^2 m_2} \cosh(2s m_1) - 2K e^{2(s - \langle x \rangle)^2 m_2} [m_1 \sinh(2s m_1) + 2s m_2 \cosh(2s m_1)]$ .

To obtain the Green's function  $G(x; x^0; t; 0)$ ,  $m_1(t)$  and  $m_2(t)$  must satisfy the above equations with the initial conditions  $m_1(0) = x^0$  and  $m_2(0) = x^0^2$ . We denote  $m(t; x^0)$  for this pair solution of the differential equation. It is easy to see that for  $\Delta = 0$ , the exact expression of the Green's function of an equilibrium system is recovered. Green's function yields the correlations and responses. The correlation functions are given by  $C(t) = \langle dx^0 x^0 m_1(t; x^0) \rangle (x^0; m)$ . Here  $\langle \cdot \rangle$  denotes the steady-state value. While the response to a pulse is  $R(t) = \langle dx^0 (D - m_2) x^0 m_1(t; x^0) \rangle (x^0; m)$ . Combining these yields the effective temperature

$$\frac{T^{eff}(t)}{T^{th}} = \frac{\partial_t C(t)}{R(t)} = \frac{1 + \frac{1}{2} \frac{K}{D} \exp[2(s - \langle x \rangle)^2 m_2]}{1 + \frac{K}{D} \exp[2(s - \langle x \rangle)^2 m_2]} + \frac{K}{2D} \frac{e^{2(s - \langle x \rangle)^2 m_2(t; x^0)} \sinh(2s m_1(t; x^0)) x^0}{m_1(t; x^0) x^0} \frac{(x^0) dx^0}{(x^0) dx^0} \quad (6)$$

Thus we see that FDT violation is a product of two ratios. One ratio is the steady-state variance compared

with the corresponding thermal equilibrium value. The other ratio depends on the rate at which the system

reaches the steady state. I.e., the larger the variance and the faster the dynamics, the hotter the system and vice versa. Compared with the cases without kicking, susceptible motors yield a smaller variance while on the other hand, they relax faster. In the short time limit,  $m_1(t; x^0) \rightarrow x^0$  and  $m_2(t; x^0) \rightarrow 0$ , and the second ratio becomes  $1 + \frac{K v^2}{D} e^{2(s^*)^2 m_2}$ . For long times,  $m_1 \rightarrow 0$ ,  $\sinh(s a m_1) \rightarrow s a m_1$ , and  $m_2 \rightarrow m_2$ . We find at this limit the value of the ratio as  $1 + \frac{K v^2}{D} e^{\frac{(s a^*)^2}{2} m_2}$ , exact same as the short time limit. Therefore  $T^{\text{eff}}(t=0) = T^{\text{eff}}(t=\infty) = 1 + \frac{1}{2} \frac{K v^2}{D} e^{2(s^*)^2 m_2}$ . Yet for intermediate times, the ratio is not constant and differs from either limiting value. Generally,  $T^{\text{eff}} > T^{\text{th}}$ , i.e., the system is "hotter" although chemical noise apparently enlarges the stability range of the localized phase.

We have studied the stability and dynamics of localized nonequilibrium structures of motorized particles. The

nonequilibrium noise from kicking motors sometimes increases the effective spring constant and enlarges the mechanical stability range of both crystal and frozen glass structures. We see that for systems like the cytoskeleton, nonequilibrium noise may speed up the dynamics without sacrificing structural stability. This model can be further developed to include anisotropy of the particles or under other types of nonequilibrium noise or driven forces. We have also studied the dynamics and effective temperatures [23] of this system. Besides taking this solid-state viewpoint, one can also study the transition from the liquid side by mode coupling theory, a problem for future works.

This work is supported by NSF and CTBP. T.S. thanks Prof. J.A.M. McCammon for his kind help and support, especially in the early stage of the work.
